Module – 08

Lecture – 46

An Introduction to Online Learning - Reinforcement Learning

(Refer Slide Time: 00:14)

Hi, so in the previous module we started looking at the multi arm bandit problems and we will continue looking at some of the solution approaches for multi arm bandits. First you recall, in this case we have n possible outcomes and we have to select one of the actions from this set of n actions and each action results in a reward derived from the probability distribution associated with the action, yet our goal is to find the most profitable action.

(Refer Slide Time: 00:46)

So, the goal could have different shades to it, so we are interested in finding the best arm, but when or how are you interested in finding the best arm. So, the simplest notion of solving the bandit problem is to identify the correct arm eventually, regardless of how many ever attempts we take as long as you can give a guarantee that eventually I will be trying the best arm that is sufficient. But, then if you want to get more practical algorithms we have to look at other notions of solving the problem.

So, look at two here, so first one is we would like to maximize the total rewards, that you obtain not just the rewards that you obtain eventually, but also the rewards that you obtain during the course of learning. So, this is called sometimes minimizing the loss or regret while learning. So, the regret is how much better you could have done, if you had known the true solution from the beginning.

So, that quantity is known as the regret and you would like to minimize the regret and the second solution concept that people look at is called probably approximately correct solutions. So, I am interested in finding an Epsilon optimal arm, the Epsilon optimal arm, is such that the mean of the selected arm mu is within Epsilon of mu star, which is the expected reward for the best arm. I am going to find an Epsilon optimal arm that gives me the approximately correct part and then, I am going to say that my algorithm will surely return the Epsilon optimal arm in 1 minus delta fraction of the problem instances.

So, the probability 1 minus delta by algorithm we give you an Epsilon optimal arm. So, for fixed values of Epsilon and delta, we try to figure out how many samples do I need

before I can give such a guarantee. So, the probably approximately correct framework that probably comes from the factor that I am interested in returning solutions with probability 1 minus delta and approximately correct, because I am interested in returning solutions with an Epsilon of the true solution.

(Refer Slide Time: 03:25)

So, there was that, the most simple traditional approach is to essentially pull the arms multiple times, keep track of the reward that you get over time. So, I would estimate mu hat i as the sum of the rewards I get and I pulled the arm i divided by the total number of times I have pulled arm i, that gives me an estimate for the average reward I expect to get when I pull arm i. And we know that, this is an unbiased estimator of the reward and hence with the enough samples as time goes to infinity, these will convergence to the true expectations and I can derive the best arm, I just looking at the arm with the maximum expectation.

To ensure that we select the arms infinitely often, we use an Epsilon 3D strategy. So, you select the arm that you currently think is the best arm, the arm star that gives you the max over all mu hat i. You select that arm with the probability of 1 minus Epsilon and Epsilon is some small constant like 0.1 or something and you can select any arbitrary arm with the probability Epsilon. So, this guarantees that every arm will get selected and therefore, as the number of place goes to infinity, then every arm gets selected infinitely often. Therefore, asymptotic convergence guaranteed for these kinds of Epsilon 3D action selection.

(Refer Slide Time: 05:12)

The one of the state of the art algorithms that you will look at is called Median Elimination algorithm, so this is a PAC algorithm. So, it gives you probably approximately correct guarantees and I tries to control the sample complexity, it is got one of the best known sample complexity for solving a multi arm bandit problem.

(Refer Slide Time: 05:40)

So, let us to get an intuition into how these things work, let us start by looking at a simple algorithm, which I will call the naive algorithm. So, you start of by sampling each arm 1 number of times, where 1 is given by the expression here. So, it is 4 by Epsilon square log 2 n by delta. So, n is the number of arms, the Epsilon will delta or the constants from your PAC results. So, you sample an arm, each arm actually 1 number of

times and let p hat be the average reward of arm a.

So, the output, this is essentially the arm that has the maximum of all the arms in the expected reward sense. So, this is; obviously, has a sample complexity of n by Epsilon square n log n by delta. The real difficulty is to show that, it actually achieves the desired performance guarantee that is with the very high probability of 1 minus delta you will return the Epsilon optimal arm and define with only probability delta. So, we will not going to, we are not going to get in to the mechanics of the proofs, it is quite beyond the scope of this course, but just I am pointing out that you can come of this simple algorithm and you can often show that they achieve the guarantees that you want.

(Refer Slide Time: 07:06)

So, one of the drawbacks of the naive algorithm is that the complexity depends on log n by delta. So, you cannot avoid the order n terms, because you have to pull each arm at least once, but you want the additional factors to be dependent only on Epsilon and delta you do not to have an additional dependence on n in your algorithm. So, Evan-Dar et al. devised an action elimination procedure, which allows you to be pretty efficient in your finding the optimal arm.

It can also serves as the basis for many other algorithm and therefore, I spend a couple of minutes looking at the median elimination algorithm. The key idea here is that, after some number of samples you are going to eliminate some arms and then, you are going to continue sampling with the rest of the arms.

(Refer Slide Time: 07:53)

So, here is the algorithm, it looks a little complex, but it is nothing really it is fairly straight forward. So, you start of by having a set of all the arms available to you start off with an epsilon and a delta and start off with 1 equal to 1 it means that your sampling 1 equal to 1, which is essentially in first round. So, here now you sample every arm that is left right. So, in the first stage it will be all the arm set this many number of times 1 by epsilon 1 by 2 square log 3 by delta 1 and let p hat a 1 denote its empirical value.

So, now, what we have done taken the arms you are pulled each of them some number of times and from that you have formed in estimate of the average in one of the arm. Now, what we do you arrange these averages in some sorted order, let us say you arrange the averages in ascending order and then, you take the first half the half that is below the median. So, the half of the data that is below the median you take those and you eliminate them.

And now, what you are left with you have half the arms, which had the highest possible expected mean from the previous round. So, now, you repeat the whole thing again except that you make your epsilon and your delta even smaller. So, with the little bit of algebra you can actually show that this gives you nice performance guarantees it gives you a PAC results, so gives you the Epsilon delta guarantees.

(Refer Slide Time: 09:48)

In addition to that you can also show that it has a sample complexity of n by epsilon square log 1 by delta we go off by epsilon square log 1 by delta. So, you got of the n in the logarithm that is a big step and it terms on that it is very hard to improve on median elimination algorithm at least using these kinds of process that we will looking at. But, in practice this kind of PAC guarantees are weak and typically you can get acceptable performance with far fewer samples and the PAC algorithm also do not cared about, how your performance varies while you are learning. And hence increasingly regret analysis of data is becoming more and more often.

(Refer Slide Time: 10:34)

So, here is a very simple algorithms that can be shown to give very good regret

performance. So, you not only maintain the best estimates or the estimate of the rewards that you have, so, far, but you also maintain some kind of an uncertainty interval around the reward. So, look at this orange curve here. So, this is the mean reward I have, but then, I also have would uncertainty or some kind of a confidence interval here that says that a the true reward with the very high confidence would be within this interval.

So, you can see that for some arms even though the estimated mean rewards are lower their uncertainty is much higher. And, so what we really are looking for is, so if you have the best estimate arm and the other arms played only of the upper bound of a suitable confidence interval is at least r one of the simplest approaches could be just be greedy with respect to upper confidence bounds you estimate the upper confidence bounds.

And when you take actions that have the highest upper confidence bounds with; obviously, going to the something higher than essentially this case you would played the arm red as supposed to orange and blue even though orange has the higher expected mean.

(Refer Slide Time: 12:05)

So, you can show that the sub optimal arm are played fewer than 8 by delta j times, where delta j is the difference between the optimal arm and the sub optimal arm and this allows us to come up with very efficient bounds for this upper confidence bounds algorithm UCB, so the algorithm is very simple. So, at any time you played the arm j that maximizes x j bar, which is your average reward. So, far plus this funny expression under the root 2 ln n by n j, where n is the number of arms and n j is the number of times

you have played arm j, so far.

So, that expression actually comes from estimating upper confidence bounds and this help us show that the sub optimal on can be played I will be played fewer than 8 by delta j ln n times. So, one of the implication of all of this I am giving you lot of numbers, but in practice you do not really have to worried about this numbers, because all we are interested in this figuring out with there is a fewer number of samples can I estimate what the outcome will be. And UCB essentially gets you there very quickly even though does not guarantee that it gives you the best outcome, but it reaches there in it reaches close to the best outcome pretty quickly.

(Refer Slide Time: 13:34)

So, I was talking about showing adds as one of the use cases, but if you think about it for each user you would like to show different adds you do not want to show the same add to different users. But, if you are using a single bandit algorithm that is learning the preferences of all the users that is what you end up doing. So, one solution around this is to build one bandit for each user, but given the large volumes of users there are likely to come to your page and restrictions on computation and sets there is not.

So, what we do is you typically share features across different users it could be demographic features, it could be browsing history, it could be location or it if you talking about patient data that it could be history patient history that could be variety of different features that you would share and your expected reward for getting the for pulling, then arm. Now, b represented as a function suppose to being a number is the

function of these features as suppose to being a single estimated number.

(Refer Slide Time: 14:54)

So, you can solve this in many different ways you can assume that each user is represented by a set of features that could be set of joint features of the user and of the arm the statistic used for choosing arms is now, dependent on these features this essentially what I was telling the statistic. In some cases can just be the mean reward could be the upper confidence bounds to the verities of things. So, the simplest case is to consider that for each feature combination you have a different bandit once a choice is made there is a stochastic transition to another bandit this just to make it conceptually easier.

But, that is not really the case, because each of this bandits are going to be closely interacting, because the feature value might be similar in which, case the outcomes for one bandits could be same for other bandits. So, earlier work there was on associative bandits were typically use a small number of states to encode this features and you do not really worried about functional representations for the values. So, once I have a function that is going to output a value a real value as a function of features, what would you think of doing exactly.

(Refer Slide Time: 16:14)

So, we could do linear regression, so where UCB variation, where you use linear regression to predict the mean reward and you use a upper confidence bounds to from the linear regression algorithm is called Lin UCB and on of the more popular contextual bandit algorithms out there. So, they expected reward is assume to be a linear function of the features people typically end of using ridge regression, which is 1 2 initialized linear regression to fit the parameters and you can derive upper confidence bounds for the regression fit. So, it gives better performance with lesser training data.

(Refer Slide Time: 17:00)

So, is here is a simple set of results for predicting click through rates on adds and you can see that if only one percent of the add data is available for training available for

estimating the parameters we could see that Lin UCB methods, which are this and this do much better, then regular UCB method, which nodes to this generalization across different users. So, you can see that 5 percent data again, so the Lin UCB variance are doing better, but then if you have a lot of data available for training we could see that the other methods pretty much catch up with Lin UCB. So, the idea here is that if Lin UCB you have better performance with lesser training data.

(Refer Slide Time: 17:57)

And, so people now, are looking at more powerful approximation looking at cousin approxy looking at other more complex sampling techniques lot of work go and once very active variant. So, people are looking at budgeted bandits people are looking at case where there are adversarial bandits and then, people are looking at dependencies between samples and multi slot cases and there are many, many, many different problems that people are sharing in the bandits literature.

One thing of interest is to consider, what I call a full reinforcement learning problem in the contextual bandits case. So, you have the context the user comes and picks an action and after that, which is move on to other user. But, in the full reinforcement learning problem, so you have to make a sequence of decisions before you can truly solve the problems. So, the faced with a situation or states or a set of features you take an action then, that results in the set of features being changed other you have to take another action and another action another action until the problem is solved.

So, think of the question of riding a cycle right all of you know how to ride cycle, then

think of how you will learned to ride a cycle you dint learned through supervised learning there is no body telling you how to turn the how, what a pressure to put on a peddle and what angle you should tilt to your upper body and things like that if I will telling you the technical aspects of cycling you probably learn to cycle all in get on the cycle and make sure we do not fall of or if you fall of in get hard you do not do the thing in next end and soon you are if find yourself cycling.

So, this is the essentially a form of reinforcement learning when each action you take and if you make a bad move you are just going to keep tilting take until you fall. So, each action you take causes the change in the state and you have to concentrate for that and, then continue learning. So, this is called the full reinforcement learning problem and the idea that we describe here like PAC, MDP and optimal exploration, so and so on, so forth, have been extended to the reinforcement learning problem as well.

So, here are couple of that are few tutorials and source material for learning more about bandits if you are interested, so this is the end of the module.
