Lecture – 06
Estimation of Parameters In Simple Linear Regression Model (continued)

Welcome to the lecture number six if you recall on the last lecture we had estimated the parameters beta0 and beta1 we had to further investigated their statistical properties we had proved that beta0 hat and beta1 hat are the unbiased estimators of their respective parameters and we also found their variances.

In the model they were three parameters beta0 beta1 and sigma square out of those three parameters we have estimated 2 parameters but the third parameter is still left.

(Refer Slide Time: 01:02)

Estimation of σ^2

$$\sum_{i=1}^n \hat{\epsilon}_i^2$$

Residual sum of squares = $\sum_{i=1}^n \hat{\epsilon}_i^2 \equiv SS_{res}$

$$= \sum_{i=1}^n [y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i]^2 \quad \hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x}, \quad \hat{\beta}_1 = \frac{s_{xy}}{s_{xx}}$$

$$= \sum_{i=1}^n [(y_i - \bar{y}) - \hat{\beta}_1 (x_i - \bar{x})]^2$$

$$= \sum_{i=1}^n (y_i - \bar{y})^2 + \hat{\beta}_1^2 \sum_{i=1}^n (x_i - \bar{x})^2 - 2 \hat{\beta}_1 \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})$$

$$= s_{yy} + \hat{\beta}_1^2 s_{xx} - 2 \hat{\beta}_1 s_{xy}$$

$$= s_{yy} + \hat{\beta}_1^2 s_{xx} - 2 \hat{\beta}_1 s_{xy}$$

$$= s_{yy} - \hat{\beta}_1^2 s_{xx}$$

$$= s_{yy} - \left(\frac{s_{xy}}{s_{xx}}\right)^2 s_{xx} = s_{yy} - \hat{\beta}_1 s_{xy}$$

$s_{xy} = \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})$
 $s_{yy} = \sum_{i=1}^n (y_i - \bar{y})^2$

So we start with the estimation of third parameter which is sigma square, there is a difference in estimating sigma square and the 2 parameter beta0 and beta1 by using the principal of least squares there is no involvement of sigma square in the function s beta0 beta1 that we had defined earlier, so it is not possible to differentiate s with respect to sigma s square, put it =0 and solve the equation to get the value of sigma square.

In order to obtain the least square estimate of sigma square we start with some estimator based on our guess, now the next question is how are we going to make a guess, we had discussed that residuals are the difference between observed and fitted values and sigma

square is the variance of epsilon i's so 1 option is that I can consider quantity like summation i goes around 1 to n , ϵ_i^2 and then

We try to take this expectation this will come out to be σ^2 as the function of σ^2 , then we adjusted to obtain a good estimator of σ^2 . Before doing that let me define it, so we try to define something called residual some of square and that is defined as some of square of the residual, so call it as SS_{res} , SS_{res} means some of square due to residual RES means it is a short form of residual, but before going further

Let us try to understand it this quantity have some important role in the regression analysis so we would like solve it further and let us and obtain different possible forms of some of its square due to residuals. If you try to see here this quantity is nothing, but i goes from 1 to n see here $y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i$ whole square. So, I can now make it like this, I try to substitute the value of $\hat{\beta}_0$.

Which $= \bar{y} - \hat{\beta}_1 \bar{x}$ and then this becomes $y_i - \bar{y} - \hat{\beta}_1 (x_i - \bar{x})$ whole square and this can be further written as summation i goes from 1 to n $(y_i - \bar{y})^2 + \hat{\beta}_1^2 \sum_{i=1}^n (x_i - \bar{x})^2 - 2\hat{\beta}_1 \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})$.

If you recall earlier we had defined the quantity like s_{xy} this s_{xy} was defined here has a summation of i goes from 1 to n , $(x_i - \bar{x})(y_i - \bar{y})$ on the same lines I can define s_{yy} as i goes from 1 to n , $(y_i - \bar{y})^2$, so this quantity now becomes $s_{yy} + \hat{\beta}_1^2 s_{xx} - 2\hat{\beta}_1 s_{xy}$ and this quantity is in nothing but your $s_{xx} - 2\hat{\beta}_1 s_{xy}$ and we had seen that $\hat{\beta}_0$ is this and $\hat{\beta}_1$ is s_{xy} / s_{xx} .

So can write down this s_{xy} as $\hat{\beta}_1 s_{xx}$, so this becomes here $s_{yy} + \hat{\beta}_1^2 s_{xx} - 2\hat{\beta}_1 \hat{\beta}_1 s_{xx}$, so this can be written as $s_{yy} - \hat{\beta}_1^2 s_{xx}$, this is 1 possible form, now I can replace here the value $\hat{\beta}_1$ is s_{xy} / s_{xx} and this I can further solve as $s_{yy} - \frac{s_{xy}^2}{s_{xx}}$ whole square s_{xx} and this will come to $s_{yy} - \frac{s_{xy}^2}{s_{xx}}$.

So this residual some of the squares has got several popular forms and depending on the need and situation we try to use them suitably. Now our next question is how to obtain the estimate of sigma square?

(Refer Slide Time: 07:05)

Use SS_{Res}
 $y_i = \beta_0 + \beta_1 x_i + \epsilon_i$, $\epsilon_i \sim N(0, \sigma^2)$
 $E(y_i) = \beta_0 + \beta_1 x_i$
 $V(y_i) = \sigma^2$
 y_i : Linear combination of normally distributed random variables
: Normally distributed random variable
 $y_i \sim N(\beta_0 + \beta_1 x_i, \sigma^2)$: independent
 $SS_{Res} = \sum_{i=1}^n \hat{\epsilon}_i^2$
 $\frac{SS_{Res}}{\sigma^2} \sim \chi^2(n-2)$
 $E\left[\frac{SS_{Res}}{\sigma^2}\right] = (n-2)$ or $E\left[\frac{SS_{Res}}{n-2}\right] = \sigma^2$
 $\Rightarrow \hat{\sigma}^2 = \frac{SS_{Res}}{n-2}$: An unbiased estimator of σ^2

$\chi^2 \sim \chi^2(n)$
 $E(\chi^2) = n$
 $Var(\chi^2) = 2n$

So let us try to use some of square due to residual to find out an estimate of sigma square but before that we need to find out the distribution of y_i so since we assume that our model is $y_i = \beta_0 + \beta_1 x_i + \epsilon_i$ and we have assumed that ϵ_i are following a normal 0 sigma square distribution and they are IID'S. I can write down here that expected value y_i is nothing but $\beta_0 + \beta_1 x_i$.

And we also have earlier that variance of $y_i = \sigma^2$ more over y_i 's are the linear combination of normal random variable of normal or normally distributed random variable which in our case is ϵ_i , so I can also write that y_i will also be normally distributed random variable, I can write down here y_i 's are going to follow a normal distribution with mean $\beta_0 + \beta_1 x_i$ and variant sigma square.

Now are they also IID, if you try to see they are independent but they are not identically distributed why because the distribution of y_i is depending on x_i so as the observation changes the mean of the normal distribution also changes, so y_i 's are independently distributed following our normal distribution with mean $\beta_0 + \beta_1 x_i$ and variant sigma square.

Once I can write this thing then we also know that some of squares of normal random variable follow a chi-square distribution. So if there are n random variables each of them is following a normal random variable then there are some of square will follow a chi-square distribution with n degrees of freedom, so incase if I try use this thing, this some of squares due to residual.

If you try to see this is nothing, but the sum of squares of normal random variables, so I can write down here that $ss_{residual}$ divided by σ^2 this will follow a chi-square with $n - 2$ degrees of freedom. one question comes how does 2 comes into picture, since I know that ϵ_i has they are depending on 2 unknown parameters, β_0 and β_1 , which you are estimating as $\hat{\beta}_0$ and $\hat{\beta}_1$.

So there are 2 unknown parameter which are being estimated in finding out the ϵ_i^2 , so that is why there are 2 constraints and so that degrees of freedom are reduce by 2 and the degrees of freedom of this chi-square random variable are $n - 2$. Just for the sake of your information and an quick review means we know that if there is some random variable z which following a chi-square distribution with n degrees of freedom then its mean that is respected value of z is n , that is the number of degrees of freedom.

And variance of z it is nothing but twice of n , that is the twice of the number of degrees of freedom. So if I try to find out here the mean of this quantity so I can write down here expected value of ss_{res} divided by σ^2 this is following a chi-square distribution with $n - 2$ degrees of freedom so its mean is going to $n - 2$. I can write down here or I can write down here expected value of ss_{res} , divided by $n - 2$.

$\hat{\sigma}^2 = ss_{res} / (n - 2)$, so this implies that $\hat{\sigma}^2 = ss_{res} / (n - 2)$, so this is an unbiased estimator of σ^2 . If you try to observe what we did we started with the model $y_i = \beta_0 + \beta_1 x_i + \epsilon_i$ and based on that we have three parameter β_0 , β_1 , and σ^2 all of them were unknown to us what we did we collected a sample of data and we had an observation something like $x_1, y_1, x_2, y_2, \dots, x_n, y_n$.

Based on that we have obtained the estimate of β_0 , estimate of β_1 and now we have also obtained the estimate of σ^2 these three parameters can be estimated using these three estimators, so now we can say that my model is known to us. There is now

another question when we are trying to estimate my model parameters for example we have estimated beta0 by beta0 hat and beta1 by beta1 hat.

How I can say that these are good or bad we have established that they are unbiased estimator and we also have found there variances, and we had obtained there variances like this variance of beta1 hat this was observed as sigma square upon sxx and variance of beta0 hat was observed as sigma square, 1 over n + xbar square over sxx.

(Refer Slide Time: 14:05)

Handwritten mathematical derivations showing the variance of the estimators:

$$\text{Var}(\hat{\beta}_1) = \frac{\sigma^2}{s_{xx}}, \quad \text{Var}(\hat{\beta}_0) = \sigma^2 \left(\frac{1}{n} + \frac{\bar{x}^2}{s_{xx}} \right)$$

$$\hat{\sigma}^2 = \frac{SS_{\text{res}}}{n-2}$$

$$\widehat{\text{Var}}(\hat{\beta}_1) = \frac{\hat{\sigma}^2}{s_{xx}} \quad \text{Replace } \sigma^2 \text{ by } \hat{\sigma}^2$$

↳ Estimator of $\text{Var}(\hat{\beta}_1)$

$$\text{Standard error} = \sqrt{\widehat{\text{Var}}(\hat{\beta}_1)}$$

$$\widehat{\text{Var}}(\hat{\beta}_0) = \hat{\sigma}^2 \left(\frac{1}{n} + \frac{\bar{x}^2}{s_{xx}} \right)$$

$$\text{Standard error} = \sqrt{\widehat{\text{Var}}(\hat{\beta}_0)}$$

Once we are trying to estimate the parameters on the on the basis of a sample I would also like to know what is the variability of my estimators because there can be more than 1 estimator for the same parameters that can be unbiased, but then how to choose among them. I would try to choose the estimator which has got a small variance so now I have got these 2 variances, but these are the values of the variance in the entire population.

If you try to see here this is depending on sigma square here and see here and sigma square is the value in the population, so these 2 variances are going to be unknown to us so my next objective is how do I estimate the standard errors of beta1 hat and beta0 hat. 1 option is that now since we have obtained that sigma square hat is ss res divided by n - 2, so 1 option is that I can write down the variance of beta1 hat as a sigma square

Upon sxx, but in this case I don't know the this variance, so I can do 1 thing that I can replace sigma square by sigma square hat, so this gives me an estimator of variance of beta hat, so now this is an estimator of variance of beta1 hat. Now what is the advantage that once I get a

set of data I can estimate my model parameter β_1 using the ordinary least square estimator s_{xy} upon s_{xx} and now I can also provide its standard error.

Just by taking the positive square root of estimate of variance of $\hat{\beta}_1$, so this will also give us an idea that what is the performance of my estimator in terms of the variability. Similarly I can also find out the estimate of the variance of $\hat{\beta}_0$, what I have to do I simply have to write down the variance of $\hat{\beta}_0$ and I have to replace σ^2 by $\hat{\sigma}^2$ and if I want to find out its standard error it is very simple just try to take the positive square root of estimate of variance of $\hat{\beta}_0$ that is all.

So now I have got a both the estimators $\hat{\beta}_0$ $\hat{\beta}_1$ I have shown that they are unbiased and I also have found their standard errors. So once I try write down a model give its parameter find out the estimate of all the parameter as well as standard errors up to certain extent we have obtained a model. After this thing there are some other considerations like test of hypothesis confidence interval estimation on the estimated parameters.

So that we will try to continue with those things, but before that let me try to explain you 1 more thing, we have considered here the simple linear regression model.

(Refer Slide Time: 18:34)

$y_i = \beta_0 + \beta_1 x_i + \epsilon_i$: intercept term
 $y_i = \beta_1 x_i + \epsilon_i$
 $E(y_i) = \beta_0 + \beta_1 x_i$ intercept term
 Interpretation of β_0
 If $x_i = 0$, $E(y_i) = \beta_0$: Average value of y
 $E(y_i) = \beta_1 x_i$ without intercept term
 If $x_i = 0$, $E(y_i) = 0$
 y_i : luminous of a bulb
 x_i : current when $x_i = 0$, $E(y_i) = 0$

$Y_i = \beta_0 + \beta_1 x_i + \epsilonpsilon I$, right this is a model which has got intercept. Now there can be another situation where we need to consider a model without an intercept, in that what would happen that I would try to consider the model something like $y_i = \beta_1 x_i +$

epsilon ϵ_i the first question come, what is the difference between the 2? Why should I consider the intercept term some time to be present or some time to be absent?

I will try to take up simple example and I would try to explain you for example when I consider an example of yield of a crop, for example yield of a crop depends on the quantity of the fertilizer, rain fall, temperature so on in this case if we try to put some fertilizer in the soil means our crop will increase, but on the other hand I do not put any fertilizer the soil itself has some inherent fertility and because of this I will get some yield, if you try see here what is the interpretation of here y_i .

If I try to write down here the model in terms of expectation, if I have the intercept term in the model this model is like this with intercept term and this model is something like $\beta_1 x_i$ if I do not have the intercept term, so if you try to see what is the interpretation of β_0 , β_0 is nothing, but if I say if $x_i = 0$ then expected value of $y_i = \beta_0$, so that mean β_0 is nothing but the average value of y .

In this case when am trying to put 0 fertilizer in the soil am I getting 0 outcome, on the other hand if I try take the model without intercept term that something like $\beta_1 x_i$ without intercept term, then if $x_i = 0$ then expected value of $y_i = 0$. So if I try to take an example to explain the 2 situation I can say in the case of crop when I put no fertilizer in the soil.

Still I get something so my outcome is not 0, so the average yield is not going to be 0, so in that case I would like to have model with an intercept term. On the other hand if I say that y_i is my here something like the luminous of a bulb and x_i is my current we all know that when we witch on the switch, then some current goes into the bulb and then the bulb glows, but if I put no current inside the bulb the bulb will not glow and the luminous will 0.

So in this case I know when I put x_i is equal to 0 then my average value of y_i is always 0, so in this case I would like to have a model without an intercept term. So there are situations in practice where some time I have to consider a model with intercept term and some time without intercept term and based on that I would like to show you in this simple frame work that what happens to the estimate of parameters.

(Refer Slide Time: 23:15)

$$\begin{aligned}
y_i &= \beta_1 x_i + \varepsilon_i & \varepsilon_i &\stackrel{iid}{\sim} N(0, \sigma^2) \\
&\quad \downarrow \\
&\quad \text{fixed} \\
\text{Minimize } S(\beta_1) &= \sum_{i=1}^n \varepsilon_i^2 \\
&= \sum_{i=1}^n (y_i - \beta_1 x_i)^2 \\
\frac{dS(\beta_1)}{d\beta_1} &= 0 \Rightarrow -2 \sum_{i=1}^n (y_i - \beta_1 x_i) x_i = 0 \\
&\text{or } \hat{\beta}_1^* = \frac{\sum_{i=1}^n x_i y_i}{\sum_{i=1}^n x_i^2} \quad \checkmark \\
\left(\hat{\beta}_1 = \frac{\sum_{i=1}^n y_i x_i}{\sum_{i=1}^n x_i^2} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2} \right) &\quad \checkmark \\
\rightarrow y_i &= \beta_0 + \beta_1 x_i + \varepsilon_i \\
\frac{d^2 S(\beta_1)}{d\beta_1^2} \Big|_{\beta_1 = \hat{\beta}_1^*} &> 0 \Rightarrow \hat{\beta}_1^* \text{ minimize } S(\beta_1)
\end{aligned}$$

So now in case if I try to consider here a model $y_i = \beta_1 x_i + \varepsilon_i$ all my assumption remain the same as earlier that β_1 is a parameter x_i is my face it is non-scholastic and ε_i are my IID normal 0 sigma square random errors. Right in this case my objective is to find out the parameter value β_1 , so I again use the principal of least square and I try to minimize the sum of a squares which I try to denote.

Now here S of β_1 i goes from 1 to n ε_i square and this is nothing but your i goes around 1 to n $y_i - \beta_1 x_i$ whole square. When I try to differentiate it with respective β_1 and put it = 0 this gives me - twice of summation i goes around 1 to n $y_i - \beta_1 x_i$, say $x_i = 0$ and when I try to solve it this gives me the values of here β_1 has a summation i goes from 1 to n $x_i y_i$ upon i goes from 1 to n x_i square.

This an estimator of β_1 so I can denote it as a β_1 say star hat I am trying to use here a notation star just to distinguish β_1 hat from the β_1 hat that was obtained in a model with intercept term. Because for the sake of clarity I can write down here that your β_1 hat is $\frac{\sum y_i x_i}{\sum x_i^2}$ upon $\sum x_i^2$ which was $\frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sum (x_i - \bar{x})^2}$ upon $\sum (x_i - \bar{x})^2$ whole square.

And this was obtained in the model $y_i = \beta_0 + \beta_1 x_i + \varepsilon_i$, so that there is no confusion between the 2 symbols of the β_1 hat. So now what do you observe here does this expression and this expression are the same not really they are very different, so the model of the story is that when you are trying to fit a model with intercept term and model without intercept term.

There is one parameter that the slope parameter beta1 is common, but their estimators in the 2 models they are different that you have to keep in mind. Now it is also not difficult to show that the second order of derivative of beta1 with respect to beta1 square at beta= beta hat star this comes out to be greater than 0 so this implies that beta1 hat star minimizes as beta1.

Now this beta1 star is the ordinary least square estimator of beta1 when we have no intercept in the model.

(Refer Slide Time: 26:54)

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n x_i y_i}{\sum_{i=1}^n x_i^2}$$

$$E[\hat{\beta}_1] = \frac{\sum_{i=1}^n x_i E(y_i)}{\sum_{i=1}^n x_i^2} = \frac{\sum_{i=1}^n x_i \cdot \beta_1 x_i}{\sum_{i=1}^n x_i^2} = \beta_1 \frac{\sum_{i=1}^n x_i^2}{\sum_{i=1}^n x_i^2} = \beta_1$$

$\hat{\beta}_1$ is an unbiased estimator of β_1

$$\text{Var}(\hat{\beta}_1) = \frac{\sum_{i=1}^n x_i^2 \text{Var}(y_i)}{\left(\sum_{i=1}^n x_i^2\right)^2} \quad (\text{Cross product terms} = 0)$$

$$= \frac{\sigma^2}{\sum_{i=1}^n x_i^2}$$

So now at the same time we can do a similar exercise and we try to establish the statistical properties that is finding out the unbiasedness character and the variance of beta1 star, so here is now here summation i goes from 1 to n, xi yi upon summation i goes around 1 to n xi square. So I can find out expected value of beta1 hat star this comes out to be summation I goes around 1 to n xi expected value of yi upon summation.

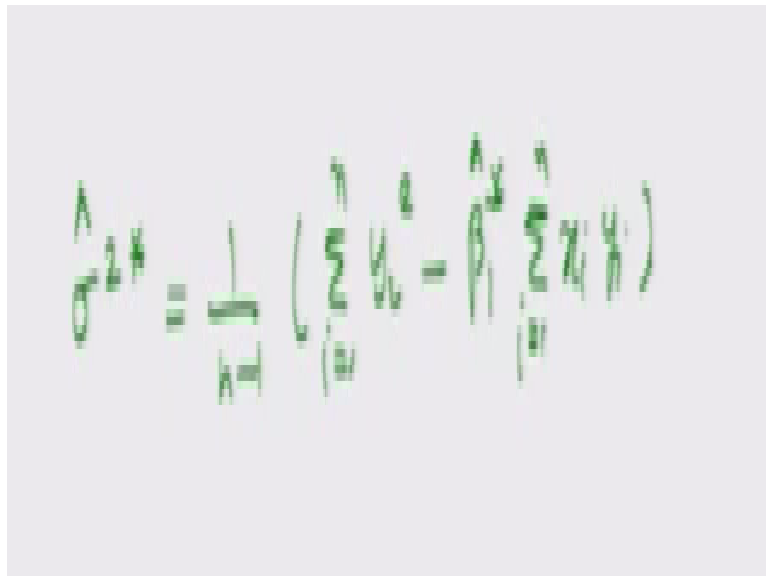

I goes from 1 to n xi square, and this quantity is nothing but i goes from 1 to n, xi an expected value of yi is nothing but beta1 xi, upon summation i goes from 1 to n, xi square. This quantity is nothing but summation i goes from 1 to n xi square upon summation i goes from 1 to n xi square and this is same as beta1 so this remains unbiased estimator, so beta1 hat star is an unbiased estimator of beta1.

That is established so there is no change in the property of unbiasedness of the slope parameter of the 2 estimators in the case of model with intercept term and model without intercept term. Similarly if I try to find out here the variance of beta1 hat star this is nothing

but summation i goes from 1 to n x_i square variance of y_i divided by summation i goes from here 1 to n , x_i square plus whole square.

And the gross product terms becomes equal to 0 because we have assumed that y_1, y_2, y_n are independent and we already established that variance of y_i is σ^2 so once I substitute this thing this comes out to be nothing but σ^2 I goes from 1 to n summation x_i square, and in this case if you also want to find out the estimate of σ^2 that can be also obtained quite easily σ^2 and let us try to say star.

(Refer Slide Time: 29:24)

$$\hat{\sigma}^2 = \frac{1}{n-1} \left(\sum_{i=1}^n y_i^2 - \beta_1^2 \sum_{i=1}^n x_i y_i \right)$$

So this can be obtained here as $\frac{1}{n-1}$ summation i goes from 1 to n y_i square - β_1 hat say star summation i goes from 1 to n $x_i y_i$. So you can see here that even the estimator of σ^2 in case of model without intercept term is quite different than the form of the estimator of σ^2 when there is an intercept term in the model.

So, the model of the story is that if you do not want to consider the intercept term in the model please don't do like this that you fit a model with intercept term and you simply substitute the intercept term $=0$ and use the same estimates. You will need to find the estimates of the parameter separately and the standard errors of the parameter estimates will also change.

So we stop here in this lecture and in the next lecture we will try to consider the maximum likelihood estimation of the parameters β_0, β_1 and σ^2 and we will try to see

how does it make a difference when we try to use different estimation techniques to estimate the parameter thank you and till then good bye.
