Now, here we will discuss also the situations where the form of the maximum likelihood estimator may not be determined explicitly it may not exist or in case of certain situations we may have non unique maximum likelihood estimator.

(Refer Slide Time: 00:46)

6.  $X_1, \dots, X_n \sim N(\theta, \theta^2) \quad \theta > 0$

$$L(\theta, z) = \frac{1}{(\sqrt{2\pi})^n \theta^n} e^{-\frac{1}{2\theta^2} \sum (x_i - \theta)^2}$$

$$\ell(\theta) = \ln L = -\frac{n}{2} \ln 2\pi - n \ln \theta - \frac{\sum (x_i - \theta)^2}{2\theta^2}$$

$$\frac{d\ell}{d\theta} = 0 \Rightarrow -\frac{n}{\theta} + \frac{\sum (x_i - \theta)}{\theta^2} + \frac{\sum (x_i - \theta)^2}{\theta^3} = 0$$

$$\Rightarrow \sum (x_i - \theta)^2 + n\theta(\bar{x} - \theta) - n\theta^2 = 0$$

Let us take say  $X_1, X_2, \dots, X_n$  follows  $n$  normal  $\theta$ ,  $\theta$  is square; that means, I am considering the situation where the mean and the standard deviation are the same. So, naturally  $\theta$  has to be positive here. Now here the likelihood function if you write then following the earlier set up it becomes  $\frac{1}{(\sqrt{2\pi})^n \theta^n} e^{-\frac{1}{2\theta^2} \sum (x_i - \theta)^2}$ .

So, the log of the likelihood function that is  $-\frac{n}{2} \ln 2\pi - n \ln \theta - \frac{\sum (x_i - \theta)^2}{2\theta^2}$ . So, what is the likelihood equation here?  $\frac{d\ell}{d\theta} = 0$  that gives  $-\frac{n}{\theta} + \frac{\sum (x_i - \theta)}{\theta^2} + \frac{\sum (x_i - \theta)^2}{\theta^3} = 0$ . Now if I consider here this term this is consisting of  $\theta$  in the numerator as well as in the denominator, so the derivative will come in 2 terms  $\sum (x_i - \theta) \cdot \frac{1}{\theta^2} + \sum (x_i - \theta)^2 \cdot \frac{-2}{\theta^3}$  is equal to 0. So, if  $\theta$  is

taken to be positive I can strike of 1 theta and we can write the equation as. So, I multiply by theta cube in the full equation and we get it as sigma x i minus theta is square, plus theta into n x bar minus theta minus n theta is square equal to 0.

Here you can see that the solution of this equation can be obtained in the terms of solution of a quadratic equation.

(Refer Slide Time: 03:11)

$$\frac{d\ell}{d\theta} = 0 \Rightarrow -\frac{n}{\theta} + \frac{\sum(x_i - \theta)}{\theta^2} + \frac{\sum(x_i - \theta)^2}{\theta^3} = 0$$

$$\Rightarrow \sum(x_i - \theta)^2 + n\theta(\bar{x} - \theta) - n\theta^2 = 0$$

The solution can be obtained as a solution of the quadratic eqn.

The solution can be obtained.

7.  $X_1, \dots, X_m \stackrel{i.i.d.}{\sim} N(\mu, \sigma_1^2)$   
 $Y_1, \dots, Y_n \stackrel{i.i.d.}{\sim} N(\mu, \sigma_2^2)$

$$L(\mu, \sigma_1^2, \sigma_2^2; \underline{x}, \underline{y}) = \frac{1}{(\sigma_1 \sqrt{2\pi})^m} e^{-\frac{1}{2\sigma_1^2} \sum(x_i - \mu)^2}$$

$$\frac{1}{(\sigma_2 \sqrt{2\pi})^n} e^{-\frac{1}{2\sigma_2^2} \sum(y_j - \mu)^2}$$

$$= \frac{1}{(2\pi)^{\frac{m+n}{2}} \sigma_1^m \sigma_2^n} e^{-\frac{1}{2\sigma_1^2} \sum(x_i - \mu)^2 - \frac{1}{2\sigma_2^2} \sum(y_j - \mu)^2}$$

$$\ell(\mu, \sigma_1^2, \sigma_2^2) = -\frac{(m+n)}{2} \ln 2\pi - \frac{m}{2} \ln \sigma_1^2 - \frac{n}{2} \ln \sigma_2^2 - \frac{1}{2\sigma_1^2} \sum(x_i - \mu)^2 - \frac{1}{2\sigma_2^2} \sum(y_j - \mu)^2$$

Let me take another example of similar nature, there the form may be even more difficult. Now this is popularly called the problem of common mean in the statistical inference. So, we have a random sample from a normal population with mean  $\mu$  and variance  $\sigma_1^2$ , and another random sample  $Y_1, Y_2, \dots, Y_n$  from a normal population with mean  $\mu$  and variance  $\sigma_2^2$ . So, in particular  $\sigma_1^2$  and  $\sigma_2^2$  may be different, but the mean is common. So, here you write down the likelihood function here 3 parameters are there:  $\mu$ ,  $\sigma_1^2$ ,  $\sigma_2^2$  and 2 samples  $x$  and  $y$  are there.

So, the likelihood function will involve  $\frac{1}{\sigma_1 \sqrt{2\pi}}$  to the power  $n$ ,  $e^{-\frac{1}{2\sigma_1^2} \sum (x_i - \mu)^2}$  and  $\frac{1}{\sigma_2 \sqrt{2\pi}}$  to the power  $n$ ,  $e^{-\frac{1}{2\sigma_2^2} \sum (y_j - \mu)^2}$ . So, the terms can be simplified  $\frac{1}{(2\pi)^{\frac{m+n}{2}}}$ ,  $\sigma_1^{-n}$ ,  $\sigma_2^{-n}$ ,  $e^{-\frac{1}{2\sigma_1^2} \sum (x_i - \mu)^2 - \frac{1}{2\sigma_2^2} \sum (y_j - \mu)^2}$ .

So, the log likelihood function is equal to  $-\frac{m+n}{2} \ln(2\pi) - \frac{n}{2} \ln \sigma_1^2 - \frac{n}{2} \ln \sigma_2^2 - \frac{1}{2\sigma_1^2} \sum (x_i - \mu)^2 - \frac{1}{2\sigma_2^2} \sum (y_j - \mu)^2$ .

(Refer Slide Time: 05:54)

$$\frac{\partial \ell}{\partial \mu} = \frac{m(\bar{x} - \mu)}{\sigma_1^2} + \frac{n(\bar{y} - \mu)}{\sigma_2^2} = 0$$

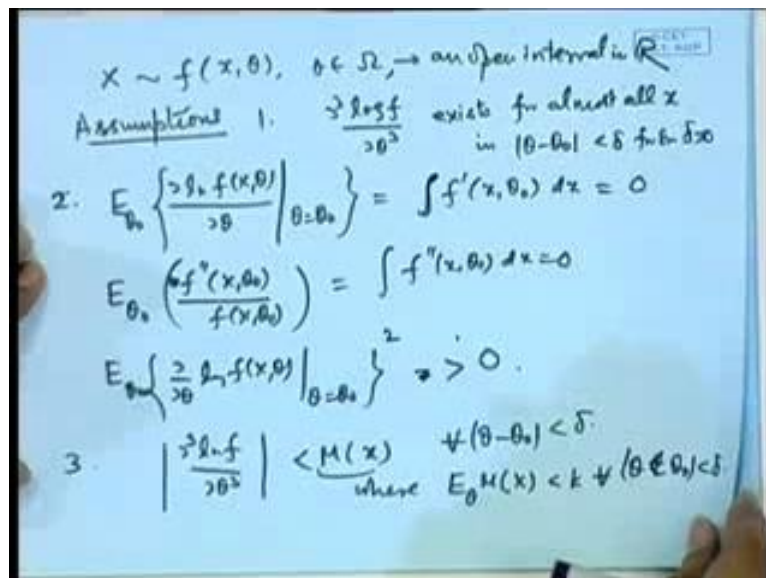

$$\frac{\partial \ell}{\partial \sigma_1^2} = -\frac{m}{2\sigma_1^2} + \frac{1}{2\sigma_1^4} \sum (x_i - \mu)^2 = 0$$

$$\frac{\partial \ell}{\partial \sigma_2^2} = -\frac{n}{2\sigma_2^2} + \frac{1}{2\sigma_2^4} \sum (y_j - \mu)^2 = 0$$

So, if we consider the likelihood equations; the equations are  $\frac{\partial \ln l}{\partial \mu} = 0$  that gives us  $\bar{x} - \mu = \frac{\sigma^2}{n}$ ,  $\bar{y} - \mu = \frac{\sigma^2}{2}$  is equal to 0. If I consider  $\frac{\partial \ln l}{\partial \sigma^2}$  that gives us  $-\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum_{i=1}^n (x_i - \mu)^2 = 0$ .

Obviously you can see that if I obtain the value of  $\mu$  here from here, it involves  $\sigma^2$  and  $\sigma^4$ . So, substituting here we get highly non-linear equation since  $\sigma^2$  and  $\sigma^4$  and the solutions for them cannot be obtained in the explicit form. So, numerical methods can be used to obtain the solutions therefore, the question arises that what are the situations where the maximum likelihood estimator will exist or it will not exist. So, we have certain regularity conditions under which the maximum likelihood estimator always exists; let me briefly mention about this here the likelihood equations. So, we state in the following form let us have the following assumptions.

(Refer Slide Time: 07:50)

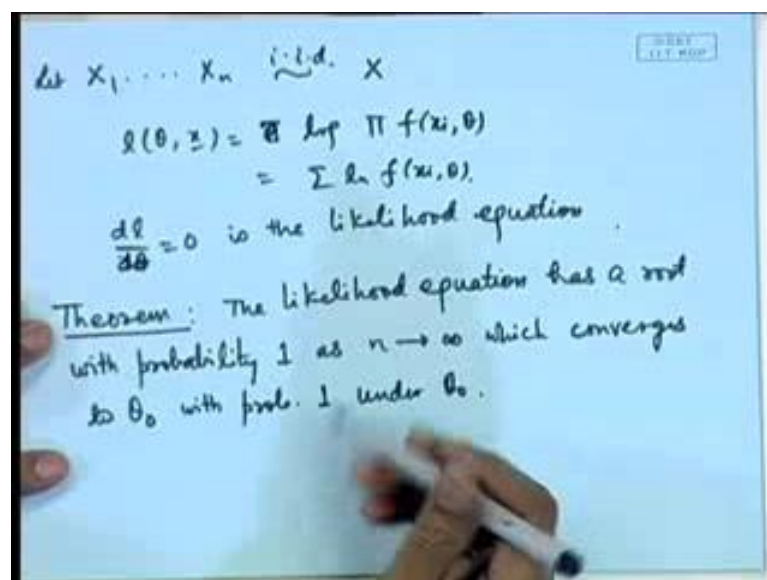

So, we consider  $X$  has a distribution  $f(x, \theta)$ , where  $\theta$  belongs to  $\Omega$  and this  $\Omega$  is an open interval in the real line so; that means, I am considering one dimensional case, the assumptions are the third order derivative respective  $\theta$  exists for almost all  $x$  in for some  $\delta > 0$ . So, around some neighborhood of a

point  $\theta_0$ ; second assumption is that at a point  $\theta_0$  this expectation becomes 0; basically it means that the density can be integrated differentiated under the integral sign, now this integral is a general notation this could be summation also in case we are dealing with the discrete distributions. So, in particular we assume up to higher order. That means, if we consider  $f''(x, \theta_0)$  by  $f(x, \theta_0)$  where this derivative is respect to  $\theta_0$  then this should also be 0 and this square is greater than 0.

And the third order derivative is bounded in a neighborhood of where  $M(x)$  is also integrable function.

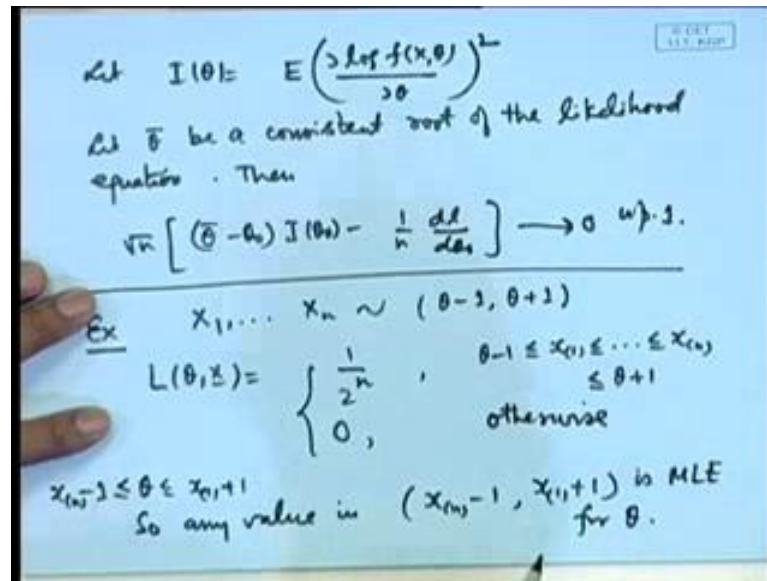

(Refer Slide Time: 10:25)

So under these assumptions on the distribution, now let us consider  $X_1, X_2, \dots, X_n$  to be i.i.d as  $X$  and we define the likelihood equation as the log of product  $f(x_i, \theta)$ , that is actually sigma, then  $\frac{dl}{d\theta} = 0$  is the likelihood equation. So, we have the following result - The likelihood equation has a root with probability 1 as  $n$  tends to infinity, which converges to  $\theta_0$  with probability 1 under  $\theta_0$ .

So, this is an important result that is under certain regularity conditions the maximum likelihood estimator can always be found and it also converges to the parameter with probability one that means it is also consistent. The second thing is that the asymptotic distribution is also normal.

(Refer Slide Time: 12:20)

So, if I define say  $I(\theta)$  as expectation of  $\frac{\partial \log f(x, \theta)}{\partial \theta}$  whole square, which is actually called the information; let  $\bar{\theta}$  be a consistent root of the likelihood equation then so we are continuing with those assumptions, the asymptotic distribution of  $\bar{\theta}$  is 0 with probability 1. We further consider the case when the maximum likelihood estimators may not be unique.

Let us take  $X_1, X_2, \dots, X_n$  follow a uniform distribution on the interval  $\theta-1$  to  $\theta+1$ . So, the likelihood function in this particular case will be equal to  $\frac{1}{2^n}$  for  $\theta-1 \leq x_1 \leq \dots \leq x_n \leq \theta+1$ . So, you can see here that  $\theta$  is less than or equal to  $x_1 + 1$  and it is also greater than or equal to  $x_n - 1$ . So, any value of  $\theta$  between these 2 limits will be maximum likelihood estimator. So, any value in the interval  $x_n - 1$  to  $x_1 + 1$  is maximum likelihood estimate for  $\theta$ . So, we have a situation here where the maximum likelihood estimator is not unique.

However for convenience one may take the average of the end points that is  $\frac{x_1 + x_n}{2}$  as the maximum likelihood estimator in this case. Now we consider the case where the techniques of direct differentiation or even considering like that the behavior of the likelihood function as an increasing function or decreasing function may not be appropriate. I am talking about the case where we may have to take each value one by

one and then check which one will give the maximum likelihood estimator; let me explain through an example.

(Refer Slide Time: 15:38)

$X \sim \text{Bin}(n, p)$   
 Find MLE of  $n$  and  $p$  if  $X$  is observed to be 1  
 $L(n, p) = n p (1-p)^{n-1}$   
 $n=2, p=1/3 \rightarrow L = 2 \cdot \frac{1}{3} \cdot \frac{2}{3} = \frac{4}{9}$   
 $n=2, p=2/3 \rightarrow L = 2 \cdot \frac{2}{3} \cdot \frac{1}{3} = \frac{4}{9}$   
 $n=3, p=1/3 \rightarrow L = 3 \cdot \frac{1}{3} \cdot \left(\frac{2}{3}\right)^2 = \frac{4}{9}$   
 $n=3, p=2/3 \rightarrow L = 3 \cdot \frac{2}{3} \cdot \left(\frac{1}{3}\right)^2 = \frac{2}{9}$   
 $(\hat{n}, \hat{p})_{ML} = (2, \frac{1}{3}), (2, \frac{2}{3}), (2, \frac{1}{3})$

Suppose I consider binomial  $n, p$  and  $n$  is either 2 or 3 and  $p$  is either 1 by 3 or 2 by 3.

Now, we want to find out the maximum likelihood estimator of  $n$  and  $p$  if  $x$  is observed to be 1. Now this is the situation where we actually write down the values of the likelihood function at each of these parameter values that is  $n$  is equal to 2  $p$  is equal to 1 by 3  $n$  is equal to 2  $p$  is equal to 2 by 3 etcetera and then see which one is the largest. So, let us write down the likelihood function here, the likelihood function here is  $n \cdot p \cdot (1-p)^{n-1}$ . So, since  $X$  is 1 so it is  $n \cdot p \cdot (1-p)^{n-1}$ . So, since  $x$  is equal to 1 is already observed we are having exactly these values. So, we have the 4 values here when  $n$  is equal to 2,  $p$  is equal to 1 by 3 corresponded to this the likelihood function is equal to twice 1 by 3 into 2 by 3 that is equal to 4 by 9.

Then  $n$  is equal to 2 and  $p$  is equal to 2 by 3 the likelihood function value turns out to be twice 2 by 3, 1 by 3 that is again 4 by 9; when  $n$  is equal to 3 and  $p$  is equal to 1 by 3 the likelihood function value is equal to 3, 1 by 3, 2 by 3 is square that is equal to 4 by 9 again and  $n$  is equal to 3,  $p$  is equal to 2 by 3; here the likelihood function value turns out to be 3, 2 by 3, 1 by 3 is square which is equal to 2 by 9. If we are looking at the maximization of the likelihood function then you can observe here that this value this

value and this value they are all same and they are the maximum this value is actually a smaller.

That means any of the configurations 2, 1 by 3, 2, 2 by 3, 3, 1 by 3 they are as likely to give the maximum value as a new other value therefore, the maximum likelihood estimator for n and p can be considered to be pair 2, 1 by 3, 2, 2 by 3, or 3, 1 by 3 now this is another case because here four possible configurations are their out of that 3 or corresponding to the maximum likelihood value.

(Refer Slide Time: 18:58)

Example:  $x_1, \dots, x_n \sim \text{Cauchy}$ .  $\frac{1}{\pi} \frac{1}{1+(x-\theta)^2}$   
 $-\infty < x < \infty$   
 $-\infty < \theta < \infty$

$$L(\theta, \pi) = \frac{1}{\pi^n} \prod_{i=1}^n \frac{1}{1+(x_i-\theta)^2}$$

$$\ell(\theta) = -n \ln \pi - \sum_{i=1}^n \ln \{1+(x_i-\theta)^2\}$$

$$\frac{d\ell}{d\theta} = \sum_{i=1}^n \left\{ \frac{x_i-\theta}{1+(x_i-\theta)^2} \right\} = 0$$

Let us take another example where the argument may follow a different path consider say  $X_1, X_2, \dots, X_n$  following say Cauchy distribution with the density function  $\frac{1}{\pi} \frac{1}{1+(x-\theta)^2}$ ; where  $x$  is any real number  $\theta$  is any real number.

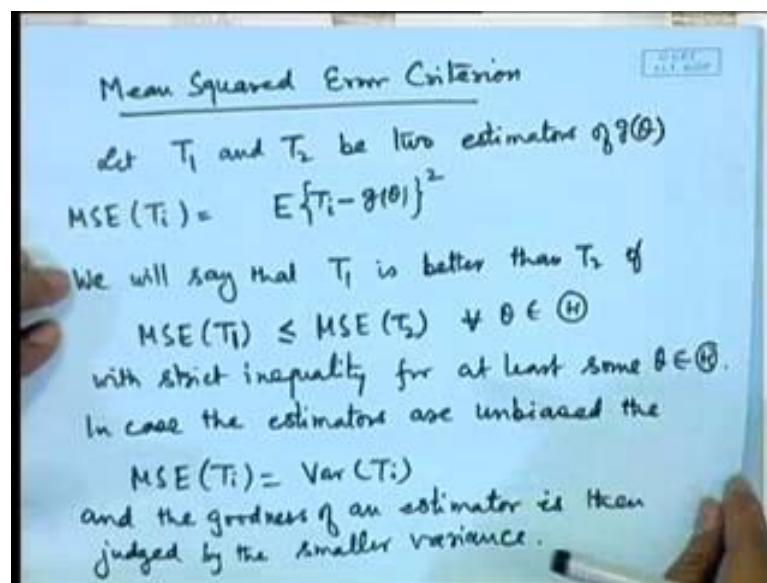

Let us look at the likelihood function that is equal to  $\frac{1}{\pi^n}$  and product  $\prod_{i=1}^n \frac{1}{1+(x_i-\theta)^2}$  is equal to  $\frac{1}{\pi^n \prod_{i=1}^n (1+(x_i-\theta)^2)}$ . So, log likelihood function is then equal to  $-\ln L = n \ln \pi + \sum_{i=1}^n \ln \{1+(x_i-\theta)^2\}$ . So, log of this term we can write it as a minus  $1$  plus  $x_i$  minus  $\theta$  is square. So,  $\frac{dL}{d\theta}$  is equal to  $0$  that is the likelihood equation will be equal to  $\sum_{i=1}^n \frac{x_i-\theta}{1+(x_i-\theta)^2} = 0$ ; you can easily see that it is a non-linear equation and the explicit solution does not exist. So, one has to use numerical methods for finding out the solution of this equation.

So, this is another example where we may not have the solution of the likelihood equation in the direct form; however, if the assumptions that we mentioned earlier or satisfied, then we can prove that the solution will exist with probability 1 and it will be consistent estimator. Now next we come to the concept of judging the goodness of the estimators. So, for judging the goodness of the estimator's one may consider the variability aspect for example, unbiasedness is one judgment because whether the estimator is biased or unbiased. So, if estimator is unbiased it will be considered to be better than the biased estimator. If an estimator is consistent another estimator is inconsistent then again we may consider the consistent estimator to be better than the inconsistent estimator.

However if we are having several consistent estimators or several unbiased estimators, then how to compare among them? So, one of the popular criteria is to look at the variability of the estimator.

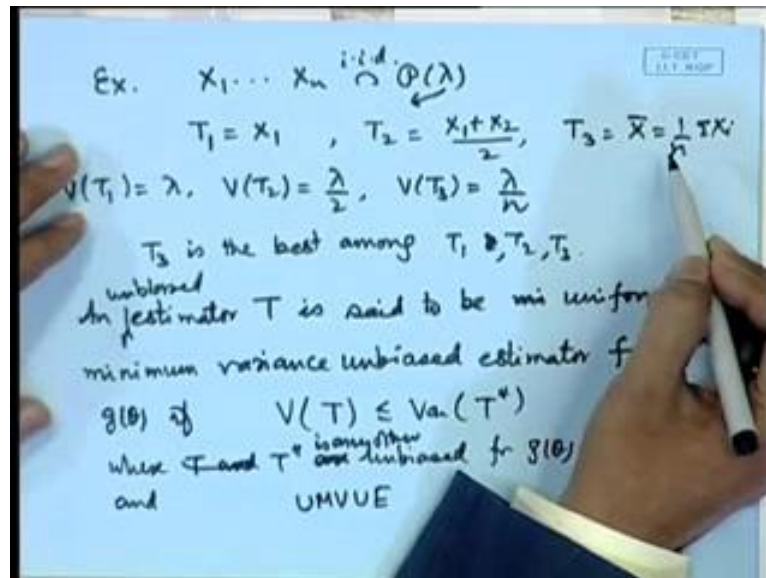

(Refer Slide Time: 21:49)

So, we have the so called mean is squared error criterion. Let  $T_1$  and  $T_2$  be two estimators of  $\theta$  say  $g(\theta)$  then the mean is squared error of  $T_i$  is defined as expectation of  $T_i$  minus  $g(\theta)$  is squared. So, this is giving a measure of variability of the estimator and we will say that  $T_1$  is better than  $T_2$  if mean squared error of  $T_1$  is less than or equal to the mean squared error of  $T_2$  for all parameters with a strict inequality for at least some  $\theta$ .

Now, if the estimators are unbiased suppose  $T_i$  is unbiased for  $g(\theta)$  then this is reducing to the variance of  $T_i$  and in that case the criteria can be written as in case the estimators are unbiased the mean squared error of  $T_i$  simply becomes variance of  $T_i$ , and the goodness of an estimator is then judged by the a smaller variance that is a smaller the variance the estimator is better.

(Refer Slide Time: 24:17)

As a simple example let us consider the exercise considered yesterday; suppose I am having  $X_1, X_2, \dots, X_n$  following say poisson  $\lambda$  distribution and I am considering estimation of  $\lambda$ . So, let me write estimator  $T_1$  as  $X_1$ , this is unbiased, let me write estimator  $T_2$  as  $(X_1 + X_2) / 2$  let me write estimator say  $T_3$  as  $\bar{x}$  which is actually the mean of all the observations.

Now, let us look at variance of  $T_1$  that is  $\lambda$ ; if I look at variance of  $T_2$  that is  $\lambda / 2$ ; if I look at variance of  $T_3$  that is  $\lambda / n$ . So, clearly here  $T_3$  is the best among  $T_1$  and  $T_2$  among  $T_1, T_2$  and  $T_3$ . So, this gives a procedure for checking that which estimators are better. Now among the unbiased estimators the one which has a smallest variance we call it minimum variance unbiased estimator. So, an estimator  $T$  is said to be uniformly minimum variance unbiased estimator for  $g(\theta)$ , if variance of  $T$  is less than or equal to variance of say  $T^*$  where  $T$  and  $T^*$  are unbiased for  $g(\theta)$ .

So, an unbiased estimator  $T$  said to be uniformly when memory is unbiased inter for  $g(\theta)$  if variance of  $T$  is less than or equal to variance  $T^*$  where  $T^*$  is any other. So,

for any other estimator if variance is smaller for  $T$ , then definitely it is having the smallest. So, we use a terminology UMVUE for example, in this case of poisson distribution  $\bar{X}$  will be uniformly minimum variance unbiased estimator.

Now the question arises that how to check that it is uniformly minimum variance unbiased estimator or how to find a uniformly minimum variance unbiased estimator because here we have already got it and then we can check, but then the total number of estimators are infinite and therefore, how to find that. So, we have to develop a method for finding out the UMVUE.

So, in the next lecture we will be considering these methods there is some additional terminology called sufficiency and completeness which is quite useful; also there are methods of obtaining lower bounds which can be found. So, in the next class we will be considering that.
