Lecture - 10
Finding Estimators- IV

Now, let me take additional cases in the case of normal distribution.

(Refer Slide Time: 00:24)

The image shows a hand holding a white marker, writing on a whiteboard. The text on the board is as follows:

$X_1, \dots, X_n \sim N(\mu, \sigma^2)$

Case I: σ^2 is known, say $\sigma^2 = 1$ (WLOG).

The likelihood function is

$$L(\mu, \mathbf{x}) = \prod_{i=1}^n f(x_i; \mu)$$
$$= \prod_{i=1}^n \left[\frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(x_i - \mu)^2} \right]$$
$$= \frac{1}{(2\pi)^{n/2}} e^{-\frac{1}{2} \sum_{i=1}^n (x_i - \mu)^2}$$

$l(\mu) = \log L(\mu, \mathbf{x}) = -$

$$\frac{\partial l}{\partial \mu} = \sum_{i=1}^n (x_i - \mu) = 0 \Rightarrow \sum_{i=1}^n (x_i - \mu) = 0$$

See here we have taken the case for estimating μ , because σ^2 was known. Now, you may have another identical situation where μ may be known and we may be interested in the estimation of σ^2 .

(Refer Slide Time: 00:45)

Case II: μ is known, say $\mu = 0$ (WLOG)

The likelihood function is

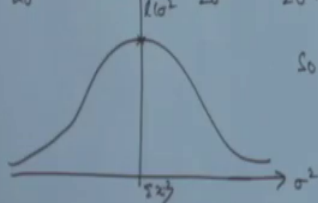

$$L(\sigma^2, \mathbf{z}) = \prod_{i=1}^n f(x_i, \sigma^2) = \prod_{i=1}^n \left[\frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{x_i^2}{2\sigma^2}} \right] = \frac{1}{\sigma^{2n} (2\pi)^{n/2}} e^{-\frac{\sum x_i^2}{2\sigma^2}}$$

$$l(\sigma^2) = \log L(\sigma^2, \mathbf{z}) = -\frac{n}{2} \log \sigma^2 - \frac{n}{2} \log 2\pi - \frac{\sum x_i^2}{2\sigma^2}$$

$$\frac{dl}{d\sigma^2} = 0 \Rightarrow -\frac{n}{2\sigma^2} + \frac{\sum x_i^2}{2\sigma^4} = 0 \Rightarrow \frac{\sum x_i^2 - n\sigma^2}{2\sigma^4} < 0 \text{ if } \sigma^2 > \frac{\sum x_i^2}{n}$$

$$> 0 \text{ if } \sigma^2 < \frac{\sum x_i^2}{n}$$

So the MLE of σ^2 is

$$\hat{\sigma}_{ML}^2 = \frac{1}{n} \sum_{i=1}^n x_i^2$$

So, let us look at this situation then say μ is known. If μ is known, then without loss of generality we may put μ equal to 0 because we can always shift all the observations by μ naught. For example, if I say that μ is known equal to μ naught then we may put it equal to 0.

So, now you look at the likelihood function, notice here the problem gets modified in the maximum likelihood estimation as soon as the information about the parameters is changed. So, the likelihood function is the product of the density functions of x_1, x_2, \dots, x_n that is equal to $\frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{x_i^2}{2\sigma^2}}$ for $i = 1$ to n .

So, we can write it in a more compact fashion. It becomes equal to $\frac{1}{\sigma^{2n} (2\pi)^{n/2}} e^{-\frac{\sum x_i^2}{2\sigma^2}}$. Notice here that σ is occurring in the denominator as well as it is occurring in the denominator of the exponent. Therefore it is beneficial to consider the log likelihood function that is equal to $-\frac{n}{2} \log \sigma^2 - \frac{n}{2} \log 2\pi - \frac{\sum x_i^2}{2\sigma^2}$.

So, we considered the likelihood equation that is $\frac{dl}{d\sigma^2} = 0$. So, so when you differentiate this you get $-\frac{n}{2\sigma^2} + \frac{\sum x_i^2}{2\sigma^4} = 0$. Notice here that I am considering σ^2 as a parameter, one may be misled by considering σ as a parameter, and then you may

be getting a slightly different derivative here. So, later on we will show that the two procedures will lead to the same answer, the identical answer. That means, whether you are considering estimation of sigma or you are considering estimation of sigma square, it should not lead to contradictory statements.

Now, we write it in a slightly modified fashion $\sum x_i^2 - n \sigma^2$ by twice sigma to the power four. So, notice here this will be less than 0 if sigma square is greater than $\sum x_i^2 / n$; and it is greater than 0 if sigma square is less than $\sum x_i^2 / n$.

So, if we look at the plot of the likelihood function, then naturally the likelihood function is increasing up to $\sum x_i^2 / n$, because the derivative is positive for sigma square less than $\sum x_i^2 / n$. So, it is increasing up to this, and there after it is decreasing. So, the maximum occurs at $\sum x_i^2 / n$. So, the maximum likelihood estimator of sigma square is we will write $\hat{\sigma}^2$ just to denote that it is the maximum likelihood estimator that is turning out to be $\sum x_i^2 / n$.

Now, you can look at the variation in place of mu is equal to 0 if we had put mu is equal to mu naught, then what would have been the modification. Here, we would have got $\sum (x_i - \mu_0)^2$. Therefore when we considered the derivative here we would have got then increasing and decreasing nature for $\sum (x_i - \mu_0)^2 / n$. Thereby, the answer would have been $\sum (x_i - \mu_0)^2 / n$.

So, now once again let me show you the effect of the prior information in this. Suppose on sigma square we have certain information because as you know sigma square is the variance. Now, the variances are the reciprocal of that is known as the precision. So, the variability may be known in advance or it may have certain restrictions.

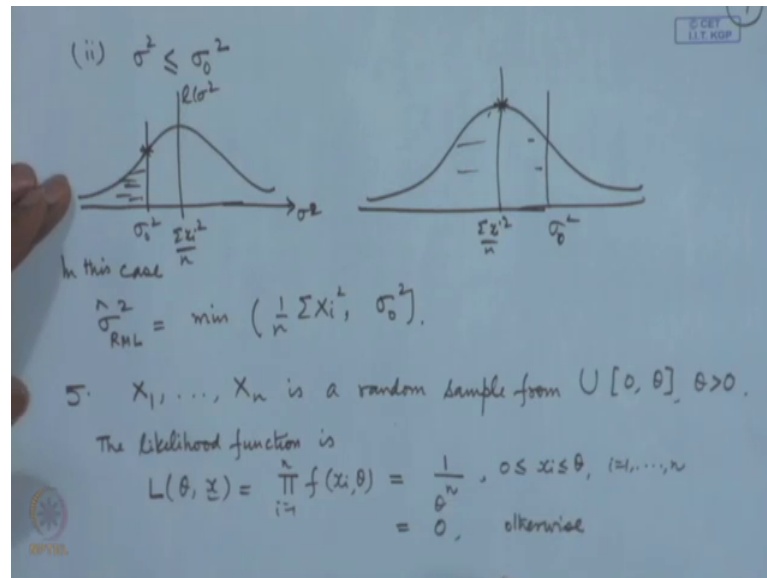

(Refer Slide Time: 06:02)

For example, we may consider say restrictions on sigma square. Say for example, sigma square may be greater than or equal to sigma naught square. Now, if you consider sigma square greater than or equal to sigma naught square, then in this case there will be two cases, because sigma naught square may occur here are sigma naught square may occur here.

So, let us see. This is sigma x i square by n, and it may happen that sigma naught a square is here. So, in this case, the maximum occurs at this point. Whereas, if sigma naught a square occurs here, in that case our region of maximization is here because sigma square is greater than or equal to sigma naught a square, in that case the maximum will occur at sigma naught square. So, we conclude that sigma hat square restricted m l is equal to sigma x i square by n if sigma square if sigma x i square by n is greater than or equal to sigma naught square. It is equal to sigma naught square if sigma x i square by n is less than sigma naught a square. That means, we can write it as maximum of sigma x i square by n and sigma naught square. In a similar way, one may considered the case of an upper bound on sigma square.

(Refer Slide Time: 08:03)

Let me take sigma square less than or equal to sigma naught square. So, once again if we look at the plot of the likelihood function, in that case if sigma naught square is occurring here, now this is our region of maximization. So, the maximum will occur at sigma naught square, whereas if sigma naught square occurs here, then this is our region of maximization, and we get the maximum here.

So, in this case the maximum likelihood estimator of sigma square will be minimum of $\frac{1}{n} \sum x_i^2$ by n sigma x_i square sigma naught square. So, the effect of the information or the prior information about the parameter plays a role in the maximum likelihood estimation. And that is one important feature which distinguishes the method of maximum likelihood estimation from various other methods.

The example that I have discussed take into account that the likelihood function or the log of the likelihood function is a nice smooth function, because we are able to differentiate and carry out the usual arguments of the analysis. Now, in certain situations that may not be possible.

Let me take up another case say x_1, x_2, \dots, x_n is a random sample from uniform zero theta distribution, where theta is the unknown parameter which is certainly positive. We are interested in the maximum likelihood estimation for theta. If you recollect the method of moments estimator for theta was $2 \bar{x}$, because the mean of the uniform distribution is theta by 2. So, the first sample moment that is \bar{x} would be the method of moments

estimator for theta by 2, that means, $2 \bar{x}$ will be the method of moments estimator for theta. Let us look at the maximum likelihood estimator here.

So, the likelihood function is $L(\theta, x)$ that is equal to product of $f(x_i | \theta)$ i is equal to 1 to n . Now, this we write as $1/\theta^n$ because the density function of the uniform distribution on the interval 0 to theta it is $1/\theta$. So, it will become $1/\theta^n$. But at the same time let us not forget that each of the x_i 's lies between 0, and theta this is for i is equal to 1 to n . Now, we should also write that it is 0 at other places.

Now, a common thing which we have been applying a real that you take the log of this and differentiate with respect to theta and put equal to 0. Now, in this case what it would lead to you will get minus $n \log \theta$. And if you differentiate will get minus n/θ which you put equal to 0 will give you an absurd answer. The reason for these absurdities that we have not taken care of the full likelihood function; the full likelihood function takes into account this portion also.

(Refer Slide Time: 12:19)

We write

$$L(\theta, x) = \frac{1}{\theta^n}, \quad 0 \leq x_{(1)} \leq \dots \leq x_{(n)} \leq \theta$$

$$= 0, \quad \text{else}$$

$$\text{or } L(\theta, x) = \frac{1}{\theta^n} I_{[0, x_{(n)}]} \cdot I_{[0, \theta]}^{(x_{(n)})}$$

So L is maximized when θ is minimized which is possible when $\theta = x_{(n)}$.

So $\hat{\theta}_{ML} = x_{(n)}$ is the MLE of θ .

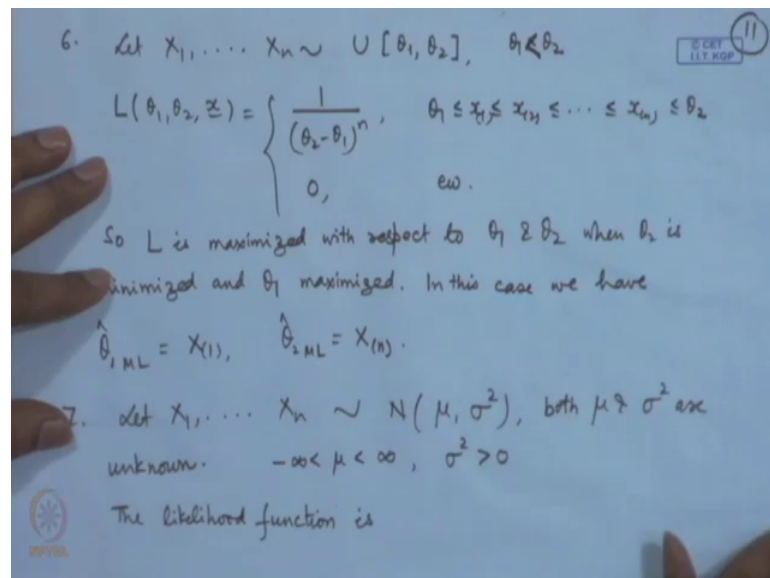

So, we write it in a slightly more compact fashion as follows. We may write the likelihood function as $1/\theta^n$ $0 \leq x_1 \leq \dots \leq x_n \leq \theta$. Or we can also write it as $1/\theta^n$ i here we can say that all the x_i 's are from 0 to x_n and multiplied by x_n itself lies between 0 to theta.

Now, if you look at the maximization of this with respect to theta, now the theta is occurring in the denominator, so that means, what is the minimum value of theta the minimum possible value of theta is $x_{(n)}$ theta cannot be below $x_{(n)}$ because of the observations each of the observations lies between 0 to theta. So, L is maximized when theta is minimized which is possible when theta is equal to $x_{(n)}$.

So, $\hat{\theta}_{ML}$ is equal to $x_{(n)}$ is the maximum likelihood estimator of theta what is the maximum of the observations. So, you can see here the result is quite different from the method of moments estimation here, because in the method of moments we would have got $2 \bar{x}$. So, this is certainly different and later on we will study the criteria that which one should be preferred here; that means, whether MME is better here, or ML is better here which one should prefer. So, we will discuss about those criteria later on.

This example shows that one should not blindly use the differentiation and put equal to 0, because this will not give the answer in this particular situation. Similar thing would occur for example, if I consider two parameter you uniform distribution.

(Refer Slide Time: 15:01)

Suppose, I take a random sample from uniform theta 1 to theta 2, where theta 1 is certainly less than or equal to theta 2. So, in this particular case, we have two unknown parameters here. And we considered the maximum likelihood estimation. So, as before we considered the likelihood function, and this will be it is equal to 0 elsewhere.

Now, you notice the likelihood function here. The likelihood function has $\theta_2 - \theta_1$ in the denominator which is the positive quantity. And we are looking at the maximization; that means, $\theta_2 - \theta_1$ should be minimum. That means, θ_2 should be minimum and θ_1 should be maximum. Now, if you look at the nature of the observations, all the observations lie between θ_1 to θ_2 . Therefore, the minimum of the observations is certainly greater than or equal to θ_1 . And the maximum of the observations is certainly less than or equal to θ_2 . So, L is maximized with respect to θ_1 and θ_2 , when θ_2 is minimized, and θ_1 maximized.

So, in this case, we have $\hat{\theta}_1$ maximum likelihood estimator is equal to the minimum of the observations. And $\hat{\theta}_2$ ML is equal to the maximum of the observations. And now this is an example where we have considered two parameter problem. So, the method of maximum likelihood estimator can be used for the maximization of the likelihood function, when there can be more than one parameter. And in that case the maximization should be considered with respect to all the parameters. So, in this case, you can see the simultaneous maximum is occurring.

Now, let us go back to the case of normal distribution that I discussed earlier here I had taken special cases. If you see carefully, if we consider normal μ σ^2 here, I have taken σ^2 to be known. So, in effect I have reduced a two one parameter problem. Similarly, if you look at μ is known, then once again the parameter has been reduced to σ^2 alone. So, in effect this problem also reduced to one parameter problem. However, in general both the parameters in a normal distribution maybe unknown and in that case let us look at the solution.

So, let me discuss in detail. So, we have x_1, x_2, \dots, x_n a random sample from normal μ σ^2 as before. However, both μ and σ^2 are unknown. So, in general you remember that in the normal distribution the mean parameter may vary from minus infinity to plus infinity and the variance parameter will be from 0 to infinity. Now, in this case when we want to find out the maximum likelihood estimator we will like to find out for both μ and σ^2 .

(Refer Slide Time: 19:48)

$$L(\mu, \sigma^2, \mathbf{x}) = \prod_{i=1}^n f(x_i, \mu, \sigma^2)$$

$$= \prod_{i=1}^n \left[\frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2\sigma^2}(x_i - \mu)^2} \right]$$

$$= \frac{1}{(2\pi\sigma^2)^{n/2}} e^{-\frac{\sum(x_i - \mu)^2}{2\sigma^2}}$$

The log-likelihood function is

$$\ell(\mu, \sigma^2) = \log L(\mu, \sigma^2, \mathbf{x}) = -\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 - \frac{\sum(x_i - \mu)^2}{2\sigma^2}$$

The likelihood equations are

$$\frac{\partial \ell}{\partial \mu} = 0 \Rightarrow \frac{\sum(x_i - \mu)}{\sigma^2} = 0 \Rightarrow \hat{\mu} = \bar{x}$$

$$\frac{\partial \ell}{\partial \sigma^2} = 0 \Rightarrow -\frac{n}{2\sigma^2} + \frac{\sum(x_i - \mu)^2}{2\sigma^4} = 0 \Rightarrow \hat{\sigma}^2 = \frac{1}{n} \sum(x_i - \hat{\mu})^2$$

So, let us write down the likelihood function. So, the likelihood function is $L(\mu, \sigma^2, \mathbf{x})$. Notice here that this has become function of both μ and σ^2 now. So, this is a joint density function as before in the earlier cases I had substituted special values of μ or σ^2 as the case was. In this case, we will have to write down the full form of the density function of a normal distribution that is $\frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2\sigma^2}(x_i - \mu)^2}$.

So, we write it in a slightly more compact fashion. This becomes $\frac{1}{(2\pi\sigma^2)^{n/2}} e^{-\frac{\sum(x_i - \mu)^2}{2\sigma^2}}$. So, it will become e to the power minus $\frac{\sum(x_i - \mu)^2}{2\sigma^2}$. Again you observe the parameters for which we need the estimators they are occurring in the exponent as well as they are occurring in the main form here.

So, it will be beneficial if we considered the log likelihood as before. So, the log likelihood $\ell(\mu, \sigma^2, \mathbf{x}) = \log L(\mu, \sigma^2, \mathbf{x})$ that is equal to $-\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 - \frac{\sum(x_i - \mu)^2}{2\sigma^2}$. This equation this function involves μ and σ^2 two variables. We need to maximize this with respect to both μ and σ^2 .

So, since this function is still very nice a smooth function, so we can still use the direct calculus method for example by taking the first order derivatives putting them equal to 0. They are giving us the likelihood equation. The solutions of that will be the points of a

minimum or maximum which we can check separately that they would be actually leading to the maximization points, they will not be the points of minimum.

So, in this case for example, we write down the likelihood equations. The likelihood equations are $\frac{\partial l}{\partial \mu}$ is equal to 0 that is $\frac{\sum (x_i - \mu)}{\sigma^2}$ is equal to 0 which we can further write because this can be easily simplified σ^2 is in the denominator that would give me $\hat{\mu}$ is equal to \bar{x} .

(Refer Slide Time: 23:18)

The handwritten notes show the following steps:

$$= \frac{1}{(2\pi\sigma^2)^{n/2}} e^{-\frac{\sum (x_i - \mu)^2}{2\sigma^2}}$$

The log-likelihood function is

$$l(\mu, \sigma^2) = \log L(\mu, \sigma^2, \mathbf{x}) = -\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 - \frac{\sum (x_i - \mu)^2}{2\sigma^2}$$

The likelihood equations are

$$\frac{\partial l}{\partial \mu} = 0 \Rightarrow \frac{\sum (x_i - \mu)}{\sigma^2} = 0 \Rightarrow \hat{\mu} = \bar{x}$$

$$\frac{\partial l}{\partial \sigma^2} = 0 \Rightarrow -\frac{n}{2\sigma^2} + \frac{\sum (x_i - \mu)^2}{2\sigma^4} = 0 \Rightarrow \hat{\sigma}^2 = \frac{1}{n} \sum (x_i - \hat{\mu})^2$$

The other equation is $\frac{\partial l}{\partial \sigma^2}$ is equal to 0 which will give me minus n by twice sigma square minus plus sigma x i minus mu square by twice sigma to the power 4 equal to 0. Which will give me sigma square is equal to 1 by n sigma x i minus mu hat square. Actually the equation is sigma square is equal to 1 by n sigma x i minus mu square, we substitute the value of mu from the first equation and substitute here.

(Refer Slide Time: 24:07)

So the MLEs of μ and σ^2 are

$$\hat{\mu}_{ML} = \bar{X} \quad \& \quad \hat{\sigma}_{ML}^2 = \frac{1}{n} \sum (X_i - \bar{X})^2$$

We may have prior information about μ , say $\mu \geq 0$.

Arguing as before, we note that

$$\hat{\mu}_{RML} = \begin{cases} \bar{X} & \text{if } \bar{X} \geq 0 \\ 0 & \text{if } \bar{X} < 0 \end{cases} = \max(\bar{X}, 0)$$

So in this case the maximum likelihood estimator of σ^2 would be modified to

$$\hat{\sigma}_{RML}^2 = \frac{1}{n} \sum \{X_i - \max(\bar{X}, 0)\}^2 = \begin{cases} \frac{1}{n} \sum (X_i - \bar{X})^2, & \text{if } \bar{X} \geq 0 \\ \frac{1}{n} \sum X_i^2, & \text{if } \bar{X} < 0 \end{cases}$$

So, the maximum likelihood estimator then turn out to be, so the maximum likelihood estimators of mu and sigma square are mu hat ML is equal to x bar and sigma hat square ML is equal to 1 by n sigma x i minus x bar whole square. In this case, you may notice at these are the same as the method of moment estimators for this particular problem. But once again as I mentioned earlier a method of maximum likelihood can take care of many other possibilities also.

For example, we may have say prior information about mu say mu is greater than or equal to 0. In that case once again we look at the likelihood function here we are getting n x bar minus mu. So, if you plot the behavior with respect to mu, then the maximum is occurring at x bar.

But if x bar is greater than 0, I will consider 0 here. And this region is coming. So, the maximum likelihood estimator will be x bar. However, if 0 occurs on this side and then we have this portion then the maximum will occur at 0. So, are going as before we know that mu hat restricted ML will be equal to x bar if x bar is greater than or equal to 0. It will be equal to 0 if x bar is less than 0, which we can actually write as maximum of x bar and 0.

Now, if we use this in that case the second equation the solution will get modified, because for sigma square the estimator was 1 by n sigma x i minus the estimator of mu.

And if the estimator for μ gets modified, immediately the estimator for σ^2 will also get modified.

So, in this case, the maximum likelihood estimator of σ^2 would be modified to $\hat{\sigma}^2_{RML}$ is equal to $\frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2$, which we can write as $\frac{1}{n} \sum_{i=1}^n x_i^2 - n\bar{x}^2$ if \bar{x} is greater than or equal to 0. And it will become $\frac{1}{n} \sum_{i=1}^n x_i^2$ if \bar{x} is less than 0. So, the placing of additional information about the parameter changes the maximum likelihood estimators.

I will consider a few more examples in the next class and also then we will see there are certain desirable properties which are basically called the large sample properties that the maximum likelihood estimator satisfy, and because of this the method has wide applicability among statisticians. So, in the tomorrow's class we will consider various properties of the maximum likelihood estimators. And then, we will proceed to determining the criteria for judging the goodness of the estimators.

Thank you today.
