Lecture – 13
Properties of MLES - I

In the last lectures, I have derived the form of the maximum likelihood estimators for various probability models. I have demonstrated how the role of likelihood is there in determining the final form of the estimator. Suppose, there is a prior information, then it has a effect. Now, in today's lecture, I will spend some time on discussing important properties of the maximum likelihood estimators. First of all, we note that see various problems we have done and in most of those problems you have got a value of the maximum likelihood estimator; that means, there is a function which is corresponding to the estimator. However, that is not necessarily the case; sometimes we may have a non uniqueness.

(Refer Slide Time: 01:06)

So, let me give an example of that non uniqueness of the MLE. Let me discuss one example of that let we have a sample X_1, X_2, \dots, X_n from a uniform distribution on the interval $\theta - a$ to $\theta + a$ where θ is a real number and a is a positive number, here a is a known constant. So, the problem is here to estimate the parameter θ of this uniform distribution; that means, the spread is from $\theta - a$ to $\theta + a$

plus a . Since, θ is unknown; we do not know the starting and the end point of the spread.

So, let us consider the likelihood function. The likelihood function is now here the density function is $\frac{1}{2a}$. So, if I consider the joint distribution of X_1, X_2, \dots, X_n , it will become $\frac{1}{2a}$ to the power n and each of the X_i lies from $\theta - a$ to $\theta + a$. Therefore, we can summarize this information in the form that $\theta - a \leq x_1$ and so on, $\theta - a \leq x_n \leq \theta + a$. Let me put it here closed interval because I am including the endpoints here it is equal to 0 elsewhere.

Naturally, you can see that the maximum value of the likelihood function is $\frac{1}{2a}$ to the power n because, this is a constant value here at other points it is 0. Now, this is satisfied then this inequality holds true. Therefore, let us see the optimal range of θ for which this value is attained. So, L is maximum when $\theta - a \leq x_1$ or you can say that $\theta \leq x_1 + a$ and $\theta + a \geq x_n$ or $\theta \geq x_n - a$.

Naturally, if I choose any value of θ in the interval $x_n - a$ to $x_1 + a$ that will be the maximum likelihood estimator. So, any value of between $x_n - a$ to $x_1 + a$ is a maximum likelihood estimator of θ . So, this is an example where the maximum likelihood estimator is not unique.

However, we may choose the for example, the midpoint of this that will be $\frac{x_1 + x_n}{2}$. We may choose the midpoint that is $\frac{x_1 + x_n}{2}$ as the MLE.

Now, another feature which we noticed in the various problems that we have done that in most of the cases, we got it a very nice function. For example, we got it as $\frac{1}{\sigma^n} \exp\left(-\frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \bar{x})^2\right)$ the median, the largest or the smallest etcetera. In most of these cases the maximum likelihood estimator is in a closed form and also a mathematically elegant form, but even that is not necessary.

(Refer Slide Time: 05:30)

MLE need not be in a nice analytic form.

Let $X_1, \dots, X_n \sim N(\theta, \theta^2), \theta > 0$

$$L(\theta, \underline{x}) = \frac{1}{(\theta\sqrt{2\pi})^n} e^{-\frac{1}{2\theta^2} \sum (x_i - \theta)^2}, \quad x_i \in \mathbb{R}, \theta > 0$$

$$\ell(\theta) = \log L(\theta, \underline{x}) = -n \log \theta - \frac{n}{2} \log 2\pi - \frac{\sum (x_i - \theta)^2}{2\theta^2}$$

$$\begin{aligned} \ell &= -\frac{n}{\theta} + \frac{\sum (x_i - \theta)}{\theta^2} + \frac{\sum (x_i - \theta)^2}{\theta^3} \\ &= \frac{1}{\theta^3} \left[\sum (x_i - \theta)^2 + \theta \sum (x_i - \theta) - n\theta^2 \right] \\ &= \frac{1}{\theta^3} \left[\sum x_i^2 - 2n\theta \bar{x} + n\theta^2 + n\theta \bar{x} - n\theta^2 - n\theta^2 \right] \\ &= \frac{1}{\theta^3} \left[\sum x_i^2 - n\theta \bar{x} - n\theta^2 \right] \end{aligned}$$

Let me take another example where we do not get a nice analytic form, MLE need not be in a nice analytic form. Let me take one example here. Let X_1, X_2, \dots, X_n be a random sample from a normal distribution with mean, θ and variance θ^2 .

So, naturally here θ is a positive parameter here, the likelihood function. So, here your variance is actually the square of the mean. So, there is an interrelationship here. So, the problem reduces to one parameter. So, if we consider the likelihood function, it is a joint distribution $\frac{1}{(\theta\sqrt{2\pi})^n} e^{-\frac{1}{2\theta^2} \sum (x_i - \theta)^2}$ and here each of the x_i is on the real line whereas, θ is positive.

So, if we consider the log likelihood that is equal to $-n \log \theta - \frac{n}{2} \log 2\pi - \frac{\sum (x_i - \theta)^2}{2\theta^2}$. There is naturally a difference from the situation when we had considered μ, σ^2 because then we had two parameters and we had considered the maximization with respect to both of them. Now, since μ has been replaced by θ , so, this is a consolidated function of θ that is coming here and we have to maximize this with respect to θ , but nevertheless this is a differentiable function and therefore, we can think of the usual calculus procedure.

Let us look at $\frac{d}{d\theta} \ell(\theta)$. So, that is equal to $-\frac{n}{\theta} + \frac{\sum (x_i - \theta)}{\theta^2} + \frac{\sum (x_i - \theta)^2}{\theta^3}$

cube because the derivative of $1/\theta^2$ will be $-2/\theta^3$. So, that simplifies to this. This term we can write as $\sum x_i^2 - 2\theta \sum x_i + n\theta^2$ divided by θ^3 .

Now, we can expand these terms here, you will get $1/\theta^3 \sum x_i^2 - 2\theta \sum x_i + n\theta^2$. Now, you get $2\theta \sum x_i$ when you put summation here it becomes $\sum x_i$ which we can write as $n\bar{x}$. So, $-2n\theta\bar{x}$, then you have $\theta \sum x_i$ again which you can write as $n\theta\bar{x}$. So, this becomes $n\theta\bar{x} - 2n\theta\bar{x} + n\theta^2$ and this is summation here. So, $-n\theta\bar{x} + n\theta^2$ and of course, there was another term here which we missed here, $1/\theta^3 \sum x_i^2$. So, $n\theta^2$ will come here with a plus sign plus $n\theta^2$.

So, naturally this term cancels out and here one of the $n\theta\bar{x}$ cancels out, we get here $1/\theta^3 \sum x_i^2 - n\theta\bar{x} + n\theta^2$. Now, we can consider the if we put this equal to 0, then this is nothing but a quadratic equation in θ which will have two roots because the denominator is θ^3 which is always positive.

(Refer Slide Time: 09:58)

So, we can look at this $dL/d\theta = 0$ gives θ is equal to. So, we can write this equation the $\sum x_i^2$ term is coming we can take out n here. So, this we can write as $-n\theta\bar{x} + n\theta^2 + \frac{1}{\theta^3} \sum x_i^2$, I will use the notation α_2 . This α_2 notation we have introduced in the

method of moments. This is the second sample moment, this α^2 is $\frac{1}{n} \sum x_i^2$.

So, if we put this equal to 0 we can straightforwardly apply the $b^2 - 4ac$ formula. So, we get θ is equal to $-\bar{x} \pm \sqrt{\bar{x}^2 + 4\alpha^2}$ divided by 2. So, naturally there are two solutions and we have to see the increasing and the decreasing nature of this. So, we can express $\frac{d l}{d \theta}$ as equal to $-\frac{n}{\theta^3} (\theta - \hat{\theta}_1)$ where I am taking $\hat{\theta}_1$ to be the solution with the negative that is $-\bar{x} - \sqrt{\bar{x}^2 + 4\alpha^2}$ divided by 2 and $\hat{\theta}_2$ is equal to $-\bar{x} + \sqrt{\bar{x}^2 + 4\alpha^2}$.

Now, let us look at the sign scheme of this. This term will be negative if θ is less than $\hat{\theta}_1$ or θ is greater than $\hat{\theta}_2$ because if θ is less than $\hat{\theta}_1$, this term is negative here we can see that $\hat{\theta}_1$ is less than $\hat{\theta}_2$. So, if we are considering $\hat{\theta}_1$ and $\hat{\theta}_2$ here. So, if θ is below $\hat{\theta}_1$ and θ to $\hat{\theta}_2$, then both of these terms are negative their product is positive. So, this entire term $\frac{d l}{d \theta}$ will become negative. Similarly, if θ is greater than $\hat{\theta}_2$ then this term is positive as well as this term is positive. So, the overall term will become negative and this will become positive, if $\hat{\theta}_1$ is less than θ is less than $\hat{\theta}_2$.

Therefore, we can look at the behavior of the likelihood function as θ varies of course, we can actually plot it here $\hat{\theta}_1$ will be somewhere here because both the terms are negative here, $-\bar{x}$ of course, $-\bar{x}$ could be because \bar{x} can be negative or positive; so, but this term is certainly negative and it is bigger. So, naturally I think this will become negative whereas, $\hat{\theta}_2$ is going to be positive.

The function is decreasing before θ less than $\hat{\theta}_1$. So, something like this and then it will between $\hat{\theta}_1$ to $\hat{\theta}_2$ it increases and from $\hat{\theta}_2$ onwards again it will start decreasing. So, you can see that at θ is equal to $\hat{\theta}_2$, we get a maximizing value. So, we can see that $l(\theta)$ is maximized at θ is equal to $\hat{\theta}_2$ and another point which we notice here that this is actually a positive value and from our model that we have considered here, θ should be positive. So, it is natural that our maximum likelihood estimator conforms to that range here and it is happening here.

So, the maximum likelihood estimator is $\bar{X} + \sqrt{\bar{X}^2 + \frac{4}{\alpha^2}}$. Naturally, you can see that the form of the maximum likelihood estimator is not in a nice analytic form. In fact, you are getting a square root. So, once again taking expectations etcetera checking whether it is unbiased and all those things will be quite complicated. So, the statement that maximum likelihood estimator need not be in a nice analytic form.

We may have even more difficult situation that is we may not be able to solve the likelihood equation. In this case, although solution is coming it is not in a good form, but there may be a situation where we may not be able to solve it explicitly.

(Refer Slide Time: 15:37)

MLE may not be in a closed form
 Let $X_1, \dots, X_n \sim \text{Gamma}(r, \lambda)$
 Case: λ is known and r is unknown ($\lambda=1$)

$$L(r, \underline{x}) = \prod_{i=1}^n \left[\frac{\lambda^r}{\Gamma(r)} e^{-\lambda x_i} x_i^{r-1} \right]$$

$$= \frac{\lambda^{nr}}{(\Gamma(r))^n} e^{-\lambda \sum x_i} (\prod x_i)^{r-1}$$

$$\ln L = nr \ln \lambda - n \ln \Gamma(r) - \lambda \sum x_i + (r-1) \sum \ln x_i$$

$$= -n \ln \Gamma(r) - \sum x_i + (r-1) \sum \ln x_i$$

$$\frac{dL}{dr} =$$

So, let me give an example of that situation also MLE may not be in a closed form. Let us consider say a random sample from a gamma distribution with parameter say r and λ . Now, there can be two cases as we have seen earlier; r could be known, λ may be unknown and r could be unknown and λ may be known or both may be unknown. Let us consider the case λ is known and r is unknown. If λ is known, since it is occurring at a scale parameter we may take it to be 1.

Now, let us consider the likelihood function. So, likelihood function will be a function of r now λ to the power r by r gamma r e to the power minus λx_i x_i to the power r minus 1 product i is equal to 1 to n . So, this if you take λ to the power nr by $\Gamma(r)^n$ to the power n e to the power minus $\lambda \sum x_i$ product x_i to the

power r minus 1. Let us take the log of this that is equal to $n r \log \lambda$ plus minus $n \log \Gamma(r)$ minus $\lambda \sum x_i$ plus $(r-1) \sum \log x_i$. Now, let us put λ is equal to 1 here, then this term becomes much simpler this particular term vanishes here you get minus $n \log \Gamma(r)$ minus $\sum x_i$ plus $(r-1) \sum \log x_i$.

(Refer Slide Time: 18:15)

Let $X_1, \dots, X_n \sim \text{Gamma}(r, \lambda)$
 Case: λ is known and r is unknown ($\lambda=1$)

$$L(r, x) = \prod_{i=1}^n \left[\frac{\lambda^r}{\Gamma(r)} e^{-\lambda x_i} x_i^{r-1} \right]$$

$$= \frac{\lambda^{nr}}{(\Gamma(r))^n} e^{-\lambda \sum x_i} (\prod x_i)^{r-1}$$

$$\log L = nr \log \lambda - n \log \Gamma(r) - \lambda \sum x_i + (r-1) \sum \log x_i$$

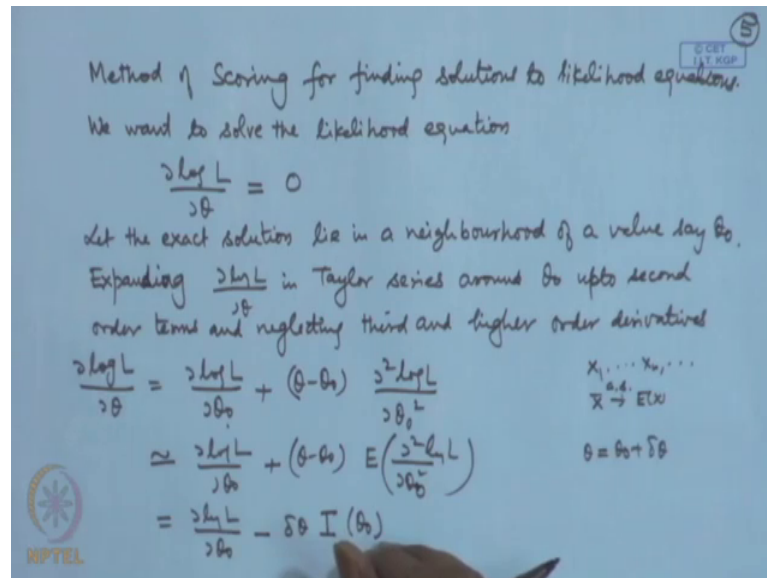

$$= -n \log \Gamma(r) - \sum x_i + (r-1) \sum \log x_i$$

$$\frac{dL}{dr} = -\frac{n \Gamma'(r)}{\Gamma(r)} + \sum \log x_i = 0 \quad \text{Euler's digamma fn.}$$

Now, if we treat it as a function of r , then derivative of this with respect to r will give me minus n by $\Gamma(r)$ into $\Gamma'(r)$. This is known as digamma function minus this will become 0 plus $\sum \log x_i$. So, this if you put 0 $\Gamma'(r)$ by $\Gamma(r)$, this is known as Euler's digamma function. So, it is not a very nice analytic function and you cannot solve that this is equal to what will be the solution. You will have to use a numerical method such as say Newton Raphson method or any other numerical method to solve this non-linear equation.

Now, in the cases when the explicit solution of the likelihood equation is not possible, a modification to the Newton Raphson method was suggested by Fisher and this is known as the method of scoring, the method of scoring for finding solutions to likelihood equations.

(Refer Slide Time: 19:20)

So, the method is briefly as follows.

We are actually looking at $\frac{\partial \log L}{\partial \theta} = 0$, we are trying to solve this equation. So, in case the solution is existing, there is no problem; however, there may be cases when the solution exists but we are not able to get exact analytic form. So, what we will do, consider we want to solve the likelihood equation $\frac{\partial \log L}{\partial \theta} = 0$ and suppose the exact solution lies in the neighborhood of θ_0 or you can say it lies at θ_0 , it could be θ_0 or it could be we can assume that it is near about θ_0 .

Let the exact solution lie in a neighborhood of a value say θ_0 . Now, once again here we will use the techniques of analysis to determine. So, for example, if we want to find out the roots of an in general non-linear equation then what do we do? We study the behavior of the function, for example, if we are saying $f(x) = 0$, then we look at the behavior of the function we try to locate the roots where they may be lying and then we apply any numerical method. Because generally, the initial approximation is important for example, in Newton Raphson method in one initial approximation is required. If we are using say bisection method, then two initial approximations are required such that both of them are on the either side of the solution.

So, similarly here we guess the initial root say θ_0 and let us consider expansion expanding say $\frac{\partial \log L}{\partial \theta}$ in Taylor series around θ_0 . Now, once we

say Taylor series expansion, we are making the assumption that the derivatives of this exist. So, let us consider only up to second order, up to second order terms and neglecting third and higher order derivatives. So, basically, it means the derivative evaluated at theta naught; similarly, here it means the derivative evaluated at theta naught, the second derivative. Now, this term what Fisher suggested we approximate by; that means, in place of this term we have written expectation. Now, there are certain justifications for this.

For example this likelihood function is the joint distribution. So, when we are taking log it is becoming summation here. So, this becomes summation term here. Now, we know by the laws of large numbers that if I have X_1, X_2, \dots, X_n a sequence of IID random variables then \bar{X} converges to expectation \bar{X} almost surely that is with probability 1; that means, if n is large enough, this approximation is all right. So, we have replaced this term by it is expectation and this expect expectation of this with a minus sign is known as the Fisher's information. So, this is equal to $\frac{\partial}{\partial \theta} \log L$ by $\frac{\partial}{\partial \theta}$ theta naught minus now this theta point we consider in the neighborhood of theta. So, let us write it as $\delta \theta$. So, this is $\delta \theta$ and minus expectation this is called Fisher's information at the point theta naught.

(Refer Slide Time: 25:02)

The equation yields

$$\delta \theta = \frac{\sum_{i=1}^n \frac{\partial \log L}{\partial \theta}}{I(\theta_0)}$$

So we take $\theta_1 = \theta_0 + \delta \theta$ and continue till desired level of accuracy is achieved.

Example: $f(x, \theta) = \frac{1}{\pi \{1 + (x-\theta)^2\}}$, $x \in \mathbb{R}, \theta \in \mathbb{R}$

Suppose observations 210, 195, 190, 199, 198, 202, 185, 215 are available. We want to determine the MLE of θ .

If we denote the observations by X_1, \dots, X_n , then the likelihood is

So, now from here what we get, the equation yields let me call it equation number 1; the equation 1 yields $\frac{\partial}{\partial \theta} \log L$ is equal to $\frac{\partial}{\partial \theta} \log L$ divided by I

theta naught because, what we are going to do, we are having delta log L by delta theta is equal to 0; that means, we are putting this term is equal to 0 here. So, if we put this 0 then we can simplify this and we get the first approximation delta theta as del by del theta not log L by I theta naught.

So, we take the next iterate as theta naught plus this delta theta and continue. So, theta 2 will then again become where delta theta will be evaluated at theta 1 and so on. So, continue till desired level of accuracy is achieved. So, this modified method it is known as Fisher Newton Raphson method or Fisher scoring method, I will explain it through one example. Let us consider say we have observations from a Cauchy distribution where x is any real number and theta is any real parameter. Suppose, observations 210, 195, 190, 199, 198, 202, 185 and 215; eight observations are available and we want to determine the maximum likelihood estimator of theta based on this sample.

Now, in general if we write X 1, X 2, X n then what will be the likelihood function in the case of if we denote the observations by say X 1, X 2, X n, then the likelihood function is product i is equal to 1 to n 1 by pi 1 plus x i minus theta square.

(Refer Slide Time: 28:10)

The image shows a handwritten derivation on a blue background. At the top right, there is a small box with the number 7. The derivation starts with the likelihood function $L(\theta, x) = \prod_{i=1}^n \frac{1}{\pi (1 + (x_i - \theta)^2)}$. This is followed by the log-likelihood function $l(\theta) = \log L = \sum_{i=1}^n \log \frac{1}{\pi (1 + (x_i - \theta)^2)}$. This is simplified to $= -n \log \pi - \sum_{i=1}^n \log (1 + (x_i - \theta)^2)$. The text then states "The likelihood equation is $\frac{dl}{d\theta} = 0$ ". This leads to the equation $\Rightarrow 2 \sum_{i=1}^n \frac{(x_i - \theta)}{1 + (x_i - \theta)^2} = 0 \dots (2)$. Finally, it concludes with "For $n=1$, we get $\hat{\theta} = x_1$, however for $n \geq 2$ it is a non-linear equation of degree $2n-1$ ".

So, if you take log of this, we will get sigma log of 1 by pi 1 plus x i minus theta square which we can write as minus n log pi minus sigma log of 1 plus xi minus theta whole square. So, if we look at the likelihood equation, d l by d theta is equal to 0, this is equivalent to this term will yield 0 if you differentiate and here you will get 1 by 1 plus x

i minus theta square and then derivative of that that will be 2 times x_i minus theta with a minus sign. So, we will get twice sigma x_i minus theta divided by 1 plus x_i minus theta square i is equal to 1 to n .

Now, naturally you can see here this equation you cannot solve for n greater than or equal to 2 for n is equal to 1 this will give simply theta is equal to x_1 for n is equal to 1, we get theta hat is equal to x_1 . However, for n greater than or equal to 2, it is a non-linear equation. In fact, even if you write two terms here, then you will get x_1 minus theta by 1 plus x_1 minus theta square plus x_2 minus theta divided by 1 plus x_2 minus theta square and obviously, that equation will be having terms up to theta cube in the numerator. So, in general if I am writing n terms here then n in each of the terms you will get a square in the denominator. So, if you multiply n minus 1 of them, you will get $2n$ minus 2 and then numerator.

So, this will give me a non-linear equation of degree $2n$ minus 1. So, naturally we cannot solve this theoretically. Let us apply the method of scoring in this problem. Now, method of scoring involves as we have seen just now that we should calculate the term called $I(\theta)$ theta naught. $I(\theta)$ theta naught is obtained as minus expectation del squared log L by del theta naught square.

(Refer Slide Time: 31:37)

We want to solve the likelihood equations

$$\frac{\partial \log L}{\partial \theta} = 0$$

Let the exact solutions lie in a neighbourhood of a value say θ_0 .

Expanding $\frac{\partial \log L}{\partial \theta}$ in Taylor series around θ_0 upto second order terms and neglecting third and higher order derivatives

$$\frac{\partial \log L}{\partial \theta} \approx \frac{\partial \log L}{\partial \theta_0} + (\theta - \theta_0) \frac{\partial^2 \log L}{\partial \theta_0^2}$$

$$0 \approx \frac{\partial \log L}{\partial \theta_0} + (\theta - \theta_0) E\left(\frac{\partial^2 \log L}{\partial \theta_0^2}\right)$$

$$0 = \frac{\partial \log L}{\partial \theta_0} - \delta \theta I(\theta_0) \dots (1)$$

X_1, \dots, X_n, \dots
 $\bar{X} \rightarrow E(X)$
 $\theta = \theta_0 + \delta \theta$
 $I(\theta) = -E\left(\frac{\partial^2 \log L}{\partial \theta^2}\right)$
 $= E\left(\frac{\partial \log L}{\partial \theta}\right)^2$

NPTL Likelihood for us

And that is also equal to let me write it here $I(\theta)$ is equal to minus expectation of $\frac{\partial^2 \log L}{\partial \theta^2}$. This is also equal to expectation of $\frac{\partial \log L}{\partial \theta}$ whole square so, one can do it in either way. Let us look at the calculation for this part.

(Refer Slide Time: 32:09)

We therefore apply the method of scoring here.

$$\log f = -\ln \pi - \ln(1 + (x-\theta)^2)$$

$$\frac{\partial \log f}{\partial \theta} = \frac{2(x-\theta)}{1 + (x-\theta)^2}$$

$$E\left(\frac{\partial \log f}{\partial \theta}\right)^2 = 4 E\left(\frac{(x-\theta)^2}{(1 + (x-\theta)^2)^2}\right) = \frac{4}{\pi} \int_{-\infty}^{\infty} \frac{(x-\theta)^2}{(1 + (x-\theta)^2)^2} dx = \frac{4}{\pi} \int_{-\infty}^{\infty} \frac{y^2}{(1+y^2)^3} dy$$

$$\frac{8}{\pi} \int_0^{\infty} \frac{y^2}{(1+y^2)^3} dy = \frac{8}{\pi} \int_0^{\pi/2} \frac{\tan^2 \theta \sec^2 \theta}{(\sec^2 \theta)^3} d\theta = \frac{8}{\pi} \int_0^{\pi/2} \sin^2 \theta \cos^2 \theta d\theta = \frac{1}{2}$$

$$I(\theta) = \frac{n}{2} \quad \text{So } s(\theta) = \frac{4}{n} \cdot \sum_{i=1}^n \left[\frac{(x_i - \theta)}{1 + (x_i - \theta)^2} \right]^2$$

So, we therefore, apply the method of scoring here. Now, for Cauchy distribution log of f is equal to minus log of π minus log of $1 + x$ minus θ square. So, $\frac{\partial \log f}{\partial \theta}$ is equal to twice x minus θ divided by $1 + x$ minus θ square. So, expectation of $\frac{\partial \log f}{\partial \theta}$ by $\frac{\partial \log f}{\partial \theta}$ whole square that is equal to 4 times expectation of x minus θ square divided by $1 + x$ minus θ square whole square. So, we evaluate this that is equal to 4 times integral x minus θ square divided by $1 + x$ minus θ square whole square and whole square of that multiplied by the density function of x and the density function of that is $\frac{1}{\pi} \frac{1}{1 + x$ minus θ square. So, you will get power 3 here and $\frac{1}{\pi}$ I will write here this is from minus infinity to infinity.

Now, you can easily transform this by putting x minus θ is equal to y . So, you get this as equal to $\frac{4}{\pi} \int_{-\infty}^{\infty} \frac{y^2}{(1 + y^2)^3} dy$; easily you can see that this is an even function. So, this becomes $\frac{8}{\pi} \int_0^{\infty} \frac{y^2}{(1 + y^2)^3} dy$.

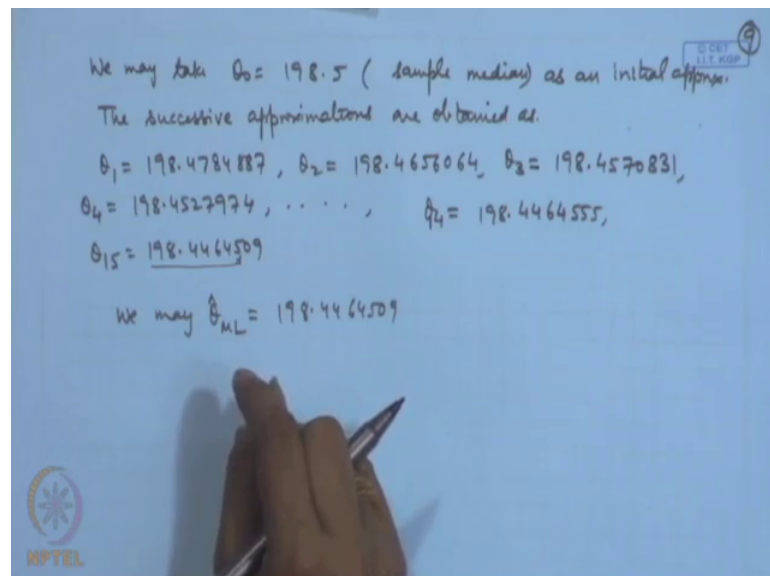

Now, this type of integral is standard we can substitute something like y is equal to $\tan \theta$. So, this will give me $\frac{8}{\pi} \int_0^{\pi/2} \frac{\tan^2 \theta \sec^2 \theta}{(\sec^2 \theta)^3} d\theta$

by $\sec^3 \theta \sec^2 \theta \frac{d\theta}{d\theta}$ and that is equal to $8 \int_0^{\pi/2} \sin^2 \theta \cos^2 \theta \frac{d\theta}{d\theta}$ and that is equal to half.

So, I, so, this you can see it is free from θ , so information at the point θ that will become $n/2$. Now, the function that you need to calculate for the scoring method is $\Delta \theta$. $\Delta \theta$ is equal to $\frac{d}{d\theta} \log L(\theta)$ divided by $I(\theta)$. So, if we look at this term here $\Delta \theta$ that will be equal to $\frac{4}{n} \sum x_i \frac{-\theta}{1+x_i^2}$ I is equal to $1/n$.

Now, the question is that what should be the initial approximation now in the Cauchy distribution. The sample mean is inconsistent because we have seen the distribution of the sample mean is the same as that of the initial observation x_i each x_i ; however, we can see that sample median will be a consistent estimator here. Now, from the given data of this the middle observation will turn out to be two middle observations are there that is 198 and 199 because there are if you arrange it in the ascending or descending order, then these are the two middle observations. So, the midpoint of that can be considered as the initial approximation.

(Refer Slide Time: 26:33)

So, we may take; we may take θ is equal to 198.5 the sample median as an initial approximation. Now, for each θ , so if I take θ here 198.5 here, we substitute n is equal to 8 and we have the data available to us x_i in the form of these

values 210, 195 etcetera. So, if you substitute these values from the initial approximation we can get the successive approximations. The successive approximations are obtained as theta 1 is equal to 198.4784887 you have done up to 7 decimal places; next approximation gives 198.4656064, theta 3 is 198.4570831; theta 4 is equal to 198.4527974 and so on.

If you look at 14, that is 198.4464555 and theta 15 is equal to 198.4464509. So, it is accurate up to five decimal places. So, we may take we may take the solution as 198.4464509. Of course, you can see that this is not much different from the sample median because, the sample median was 198.5. So, this method of a scoring can be applied to various cases whenever we are getting a non-linear equation for which the solution is not in a tractable form.
