Lecture – 16
Lower Bounds for Variance - II

(Refer Slide Time: 00:21)

Let us take another popular example that is the normal distribution. So, let us take say X_1, X_2, \dots, X_n following normal μ, σ^2 . Now, as before we will consider different cases say; $\sigma^2 = \sigma_0^2$ that is a known ok. In that case we want estimate of say UMVUE of μ . So, if we write down the distribution here $\frac{1}{\sigma_0 \sqrt{2\pi}} e^{-\frac{1}{2\sigma_0^2}(x-\mu)^2}$. So, here it will become $\sigma_0 \sqrt{2\pi} e^{-\frac{1}{2\sigma_0^2}(x-\mu)^2}$.

So, $\log f$ is equal to $-\log \sigma_0 - \frac{1}{2} \ln 2\pi - \frac{(x-\mu)^2}{2\sigma_0^2}$. So, if we consider derivative of this with respect to μ , we get simply $\frac{x-\mu}{\sigma_0^2}$. So, expectation of $\frac{\partial \log f}{\partial \mu}$ by $\frac{\partial \log f}{\partial \mu}$ whole square that is equal to expectation $\frac{(x-\mu)^2}{\sigma_0^4}$ that is equal to expectation $\frac{(x-\mu)^2}{\sigma_0^4}$ that is equal to $\frac{\sigma_0^2}{\sigma_0^4} = \frac{1}{\sigma_0^2}$. Once again in the normal distribution this is reducing to the variance term that is expectation of $(x-\mu)^2$ is variance. That is σ_0^2 by σ_0^4 that is; $\frac{1}{\sigma_0^2}$.

(Refer Slide Time: 02:14)

So $I_X(\mu) = \frac{n}{\sigma_0^2}$. So FRCLB for variance of an unbiased estimator of μ is $\frac{\sigma_0^2}{n}$.

Now \bar{X} , $E(\bar{X}) = \mu$, $V(\bar{X}) = \frac{\sigma_0^2}{n}$

So \bar{X} is UMVUE of μ .

Case II: Say $\mu = \mu_0$ is known, σ^2 ??

$$f(x, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$$

$$\log f = -\frac{1}{2} \ln \sigma^2 - \frac{1}{2} \ln 2\pi - \frac{(x-\mu)^2}{2\sigma^2}$$

$$\frac{d \log f}{d \sigma^2} = -\frac{1}{2\sigma^2} + \frac{(x-\mu)^2}{2\sigma^4} = \frac{1}{2\sigma^2} \left(\frac{(x-\mu)^2}{\sigma^2} - 1 \right)$$

So, information content in this is information contained in this will be n by sigma naught square in the sample. So, the Fisher, Rao, Cramer lower bound for variance of an unbiased estimator of μ is sigma naught square by n . Now if you consider say \bar{X} , then expectation of \bar{X} is μ . And what is variance of \bar{X} ? That is sigma naught square by n that is equal to this value.

So, \bar{X} is UMVUE of μ . Let us take another case when say μ is known and we want to estimate, say μ is equal to μ naught is known and we want sigma squares estimator. So, here the density function will be written as a function of sigma square 1 by sigma root 2π e to the power minus x minus μ square by 2 sigma square. So, log of f becomes minus half log sigma square minus half log 2π minus x minus μ square by 2 sigma square.

So, differentiation of this with respect to sigma square gives minus 1 by 2 sigma square plus x minus μ square by 2 sigma to the power 4 which I can write as, x minus μ square by sigma square minus 1 ; 1 by 4 sigma 1 by 2 sigma to the power 1 by 2 sigma square. So, if we consider expectation of.

(Refer Slide Time: 05:00)

$$E\left(\frac{\partial \log f}{\partial \sigma^2}\right)^2 = \frac{1}{4\sigma^4} E\left[\left(\frac{X-\mu}{\sigma}\right)^2 - 1\right]^2 \quad \left(\frac{X-\mu}{\sigma}\right)^2 \sim \chi_1^2$$

$$= \frac{2}{4\sigma^4} = \frac{1}{2\sigma^4}$$

$$I_X(\sigma^2) = \frac{n}{2\sigma^4} \quad \text{So FRC LB for variance of an unbiased estimator of } \sigma^2 \text{ is } \frac{2\sigma^4}{n}$$

$$T = \frac{1}{n} \sum_{i=1}^n (X_i - \mu_0)^2 \text{ is unbiased for } \sigma^2$$

$$\left(\text{as } \sum \left(\frac{X_i - \mu_0}{\sigma}\right)^2 \sim \chi_n^2, \quad E\left(\frac{nT}{\sigma^2}\right) = n \right.$$

$$\left. V\left(\frac{nT}{\sigma^2}\right) = 2n \right)$$

$$\text{Var}(T) = \frac{2\sigma^4}{n}$$

So $T = \frac{1}{n} \sum (X_i - \mu_0)^2$ is UMVUE for σ^2 .

So, if we consider expectation of del log f by del sigma square whole square. That is equal to 1 by 4 sigma to the power 4 expectation of X minus mu by sigma whole square minus 1 whole square. Once again you look at this X minus mu by sigma is a standard normal variable X minus mu by sigma it will follow chi square 1. So, expectation of this is equal to 1 and therefore, this term reduces to the variance.

So, variance is twice the degrees of freedom; that is equal to 2 by 4 sigma to the power 4. So, you get 1 by 2 sigma to the power 4. So, the Fishers information in this problem will be a n by 2 sigma to the power 4. So, the Fisher, Rao, Cramer lower bound for variance of an unbiased estimator of sigma square is 2 sigma to the power 4 by n. Now, in this case let us consider see the maximum likelihood estimator for example or the method of moments estimator.

So, that would be for example, 1 by n sigma X i minus mu naught square. So, this is now you can see here X i minus mu naught by sigma that will follow a standard normal. So, sum of squares will be chi square n. So, expectation of that is n so, this divided by n will have expectation 1. So, if we multiply by sigma square we will get sigma square. So, this is unbiased for sigma square because, we can see here as sigma X i minus mu naught by sigma whole square that follows chi square on n.

So, expectation of n T is equal to n and variance of n T. Sorry this divided by sigma square and this divided by sigma square that will be equal to 2 n. So, we will get

variance of T as equal to twice sigma to the power 4 by n because, this will go here and n square will come to know below. So, we will get 2 sigma to the power 4 by n which is same as this value once again here.

So, T is equal to 1 by n sigma X i minus mu naught square. It is the minimum variance unbiased estimator for; obviously, you can see here that if mu was not known then you could not have used this estimator. So, this solution is specific to this problem that is when we are dealing with one parameter case mu naught is known to us.

(Refer Slide Time: 08:33)

4. $X_1, \dots, X_n \sim \frac{1}{\theta} e^{-x/\theta}, \quad x > 0, \theta > 0$

$\log f(x, \theta) = -\log \theta - \frac{x}{\theta}, \quad \frac{\partial \log f}{\partial \theta} = -\frac{1}{\theta} + \frac{x}{\theta^2} = \frac{x-\theta}{\theta^2}$

$E\left(\frac{\partial \log f}{\partial \theta}\right)^2 = \frac{E(x-\theta)^2}{\theta^4} = \frac{\theta^2}{\theta^4} = \frac{1}{\theta^2}$

$I_X(\theta) = \frac{n}{\theta^2}$. ~~FRLB~~ FRLB for var of an unbiased estimator of θ is $\frac{\theta^2}{n}$.

$E(\bar{X}) = \theta, \quad V(\bar{X}) = \frac{\theta^2}{n}$

So \bar{X} is UMVUE for θ .

5. Let X have a geometric distribution
 $f(x, \theta) = \theta(1-\theta)^x, \quad x = 0, 1, 2, \dots, \quad 0 < \theta < 1$
 $\log f(x, \theta) = \log \theta + x \log(1-\theta)$

Let us consider say a random sample from exponential distribution with mean say theta. Now, in this case the density function is this. So, log of the density function is minus log of theta minus x by theta. So, the derivative with respect to theta will be minus 1 by theta plus x by theta square that is x minus theta by theta square. So, expectation of del log f by del theta whole square that is expectation of X minus theta square by theta to the power 4. In the exponential distribution with mean theta variance is equal to theta square.

So, this term becomes theta square by theta to the power 4 that is equal to 1 by theta square. So, the information in the sample about theta is n by theta square and the lower bound Fisher, Rao, Cramer lower bound for variance of an unbiased estimator of theta is theta square by n. If we consider X bar then expectation of X bar is equal to theta and variance of X bar is equal to theta square by n. So, this will prove that X bar is minimum variance unbiased estimator for theta in the case of negative exponential distribution.

It is not necessary that the lower bound is always attained. In fact, if you see carefully in each of these problems we have calculated the derivative here. So, S function you can see here for example, S would have become here $n \ln \bar{x} + \sum x_i \ln \bar{x}$ that is $n \bar{x}$. So, this is linearly related with \bar{x} and therefore, \bar{x} must attain the variance lower bound for its expectation. If you see the previous problem, for the estimation of sigma square here $\frac{\partial \log f}{\partial \sigma^2}$ is this function. So, if we look at S function $\sum x_i \sigma^2$ that would have become $-\frac{n}{2\sigma^2} \sum x_i - \frac{\mu^2}{\sigma^2}$ by something which is a linear function of $\sum x_i - \mu$ whole square.

And therefore, it is natural that $\sum x_i - \mu$ whole square by n will attain the lower bound here. So, if you see the estimation of the Poisson distribution case here the derivative is equal to $-\frac{1}{\lambda} + \frac{x}{\lambda}$. So, if you look at S function it would have become $-\frac{n}{\lambda} + \sum x_i \frac{1}{\lambda}$, which is again linearly related with \bar{x} . Therefore, \bar{x} must attain the lower bound for the variance of its unbiased estimation. So, in all these problems it is naturally coming; let me take another example where it may not be natural and therefore, the lower bound may not be attained.

Let us consider say let X have a geometric distribution and we consider the following form $\theta(1-\theta)^x$; where θ is any number between 0 and 1. So, here the problem is of estimation of θ . So, let us look at $\log f = \log \theta + x \log(1-\theta)$ that is equal to $\log \theta + x \log(1-\theta)$. So, if we consider $\frac{\partial \log f}{\partial \theta}$ we get $\frac{1}{\theta} - \frac{x}{1-\theta}$ here.

(Refer Slide Time: 13:25)

$$\frac{\partial \log f}{\partial \theta} = \frac{1}{\theta} - \frac{x}{1-\theta}$$

$$E\left(\frac{\partial \log f}{\partial \theta}\right)^2 = E\left(\frac{1}{\theta} - \frac{x}{1-\theta}\right)^2 = \frac{1}{\theta^2(1-\theta)}$$

$$I_x(\theta) = \frac{1}{\theta^2(1-\theta)}$$
 FRCLB for unbiased estimator of θ is $\frac{1}{\theta^2(1-\theta)}$.

$P(X=0) = \theta$
 Define an estimator for θ as

$$\delta(X) = \begin{cases} 1 & \text{if } X=0 \\ 0 & \text{if } X \neq 0 \end{cases}$$

Then $E\delta(X) = \theta$, $E\delta^2(X) = \theta$

$$V(\delta(X)) = \theta - \theta^2 = \theta(1-\theta) > \frac{1}{\theta^2(1-\theta)}$$
 So FRCLB is not attained.

$E T(X) = \theta$

$$\Rightarrow \sum_{x=0}^{\infty} t(x) \theta (1-\theta)^x = \theta$$

$$\Rightarrow t(0)\theta + t(1)\theta(1-\theta) + t(2)\theta(1-\theta)^2 + \dots = \theta$$

$$\Rightarrow t(0) + t(1)(1-\theta) + t(2)(1-\theta)^2 + \dots = 1$$
 Solving this we get $t(0)=1, t(1)=t(2)=\dots=0$

So, if we look at the expressions here expectation of $\frac{\partial \log f}{\partial \theta}$ we can use the moment structure of the geometric distribution. So, if we use that this is equal to expectation of $\frac{1}{\theta} - \frac{X}{1-\theta}$ by θ minus X by $1 - \theta$ whole square. So, after simplification this turns out to be $\frac{1}{\theta^2(1-\theta)}$. So, since I have taken only one observation here the information will remain the same. And the lower bound for unbiased estimator of θ is $\frac{1}{\theta^2(1-\theta)}$.

Now, here θ is not the mean actually if you look at the mean of this distribution that will be $\frac{1-\theta}{\theta}$. So, x will attain the lower bound for that for the variance of an unbiased estimator for $\frac{1-\theta}{\theta}$. But suppose we are considering estimation of θ , if we are estimating θ here then it will not be attained. So, you can see here what is the interpretation of say θ here, θ is the probability of X is equal to 0. Because if in the probability mass function we put X equal to 0 here I get θ .

So, if I define an estimator for θ as say $\delta(X)$ is equal to 1. If X is equal to 0 it is equal to 0 if X is not equal to 0; that means, if X is equal to 1, 2 and so on. Then expectation of $\delta(X)$ will be equal to $1 \cdot P(X=0) + 0 \cdot P(X \neq 0)$. That will mean it will be simply equal to θ and what is expectation of $\delta(X)^2$ that will also be θ . So, variance of $\delta(X)$ that will be equal to $\theta - \theta^2$ that is equal to $\theta(1-\theta)$.

Now here if you compare with this lower bound here, lower bound is $\theta^2(1-\theta)$ minus θ and θ is any number between 0 and 1. So, this one will be naturally bigger than this. So, the lower bound is not attained. So, we do not know whether δ is minimum variance unbiased estimator here. We may try another approach here. Let us consider expectation of $T(X)$ is equal to θ . If we consider this then we will get $\sum_{x=0}^{\infty} t(x) \theta^x (1-\theta)^{1-x} = \theta$ as x varies from 0 to infinity.

That will give me $t_0(1-\theta) + t_1\theta(1-\theta) + t_2\theta^2(1-\theta) + \dots = \theta$. Now, you look at this; what we are getting that coefficient of θ here if you see so, this you can cancel out actually $t_0(1-\theta) + t_1\theta(1-\theta) + t_2\theta^2(1-\theta) + \dots = \theta$ is equal to θ . This is true for all θ belonging to the interval 0 to 1. Now, if you see this carefully, what is the solution? See if you look at the coefficient of say θ here. θ will have coefficient t_1 ; see for example, if I look at the coefficient of the constant term, constant term is $t_0 + t_1\theta + t_2\theta^2 + \dots$ and so on that should be equal to 1.

If you take coefficient of θ then you get $-t_1 + 2t_2$. Then in the next one also $-3t_3 + 4t_4$ and so on that should be equal to 0. Then if you look at the coefficient of θ^2 you will get t_2 then here in the second one it will become $3t_3$ and so on. So, if you solve this solving this we get $t_0 = 1 - t_1 + t_2$ and so on is equal to 0 which is nothing, but this t function that is becoming same as this. So, we have proved otherwise that $T(X)$ that is equal to $\delta(X)$ is UMVUE because; this is the only unbiased estimator which we obtain through solving the equation itself.

(Refer Slide Time: 19:11)

$I_X(\theta) = \frac{1}{\theta^2(1-\theta)}$, FRC LB for unbiased estimator of θ is $\frac{1}{\theta^2(1-\theta)}$.
 $P(X=0) = \theta$.
 Define an estimator for θ as
 $\delta(X) = 1 \text{ if } X=0$
 $\quad = 0 \text{ if } X \neq 0$
 Then $E\delta(X) = \theta$, $E\delta^2(X) = \theta$
 $V(\delta(X)) = \theta - \theta^2 = \theta(1-\theta) > \frac{1}{\theta^2(1-\theta)}$.
 So FRC LB is not attained.
 $E T(X) = \theta$
 $\Rightarrow \sum_{x=0}^1 t(x)\theta(1-\theta)^x = \theta$
 $\Rightarrow t(0)\theta + t(1)\theta(1-\theta) + t(2)\theta(1-\theta)^2 + \dots = \theta$
 $\Rightarrow t(0) + t(1)(1-\theta) + t(2)(1-\theta)^2 + \dots = 1$
 Solving this we get $\theta \in (0,1)$
 $t(0)=1, t(1)=t(2)=\dots=0$
 So $T(X) = \delta(X)$ is UMVUE of θ .

However, using the method of lower bounds we are not able to prove this result here. Now many times we may not be interested directly in the theta itself, we will be interested in some function say g theta of theta; in that case what we can do is we can modify this lower bound formula like.

(Refer Slide Time: 19:56)

FRC LB for Estimating a Function $\phi = g(\theta)$ of θ .
 $\text{Var}(\delta) \geq \frac{1}{n E \left[\frac{\partial}{\partial \phi} \log f^*(x, \phi) \right]^2}$ $f(x, \theta) = f^*(x, \phi)$
 $\frac{\partial}{\partial \phi} \log f^*(x, \phi) = \frac{\partial}{\partial \theta} \log f(x, \theta) \cdot \frac{\partial \theta}{\partial \phi}$
 $\quad = \frac{\partial}{\partial \theta} \log f(x, \theta) / g'(\theta)$
 So $\text{Var}(\delta) \geq \frac{\{g'(\theta)\}^2}{n E \left(\frac{\partial}{\partial \theta} \log f(x, \theta) \right)^2} = \frac{\{g'(\theta)\}^2}{I_X(\theta)}$
 $\quad = \{g'(\theta)\}^2 \text{ (FRC LB for } \theta \text{)}$
 So the condition for attaining the FRC LB remains the same.

So, FRC lower bound for estimating a function g theta of theta, so let me call it phi. So, we will write variance of delta greater than or equal to 1 by n time's expectation del phi log of f star x phi. Because f x theta density, now I am writing as f star x phi

because we have substituted theta by g inverse phi in whatever form we are able to do that. So, if we look at this derivative here del by del phi log of f star x phi; you can apply the chain rule we can write it as del by del theta log of f x theta into del theta by del phi.

This you can write it as del by del theta log of f x theta divided by g prime theta. So, if you substitute this function here, we get variance of delta greater than or equal to g prime theta square divided by n time's expectation of del by del theta log of f X theta whole square. That is equal to g prime theta whole square by the information in the sample about theta. That means, if we have the lower bound for the variance of an unbiased estimator of theta. Then from there we can derive for any other function what we have to do, we have to multiply by the lower bound by g prime theta square.

So, this we can say it is equal to g prime theta square into the Fisher, Rao, Cramer lower bound for theta. So, this new formula can be obtained. Moreover the condition for obtaining the lower bound for attaining the lower bound, that will remain the same because the condition is coming only from the Cauchy Schwarz inequality which was dependent upon the estimator being linearly related with S X theta. Now the g theta function does not affect that thing. So, the condition for, the condition for attaining the F remains the same.

(Refer Slide Time: 27:08)

$$n E \left[\frac{\partial}{\partial \theta} \log f^*(x, \theta) \right]^2 = I_X(\theta)$$

$$\frac{\partial}{\partial \theta} \log f^*(x, \theta) = \frac{\partial}{\partial \theta} \log f(x, \theta) \cdot \frac{\partial \theta}{\partial \phi}$$

$$= \frac{\frac{\partial}{\partial \theta} \log f(x, \theta)}{g'(\theta)}$$

$$\text{So } \text{Var}(\delta) \geq \frac{\{g'(\theta)\}^2}{n E \left(\frac{\partial}{\partial \theta} \log f(x, \theta) \right)^2} = \frac{\{g'(\theta)\}^2}{I_X(\theta)}$$

$$= \{g'(\theta)\}^2 (\text{FRCLB for } \theta)$$

the condition for attaining the FRCLB remains the same.
 i.e. $\delta(x)$ must be linearly related with $S(x, \theta)$ w.p. 1.

That is your delta X that is delta X must be linearly related with S X theta with probability 1. Tomorrow's class we will be considering further properties and further

ramifications of this lower bound as well as we will see some extensions. There can be two types of extensions. One is the extension to the higher dimensions; that means, if in place of one dimensional parameter I have several dimensional parameter; then what will be the form of the Rao, Cramer inequality.

Similarly, here we have used first order derivative in the lower bound. Now, if we consider second and higher order derivatives then the level of the inequality can be changed. So, they are generalization into another direction. Another thing is that whenever we are considering differentiation, in some sense we are taking the limits. Suppose we do not take the limits in place of that we write the difference. For example, we are saying derivative so we are writing down the value of the function at 2 points θ and $\theta + \delta$ say.

So, we consider the difference there and then look at the inequality that inequality will be called the equality without the regularity condition. Because when we are having regularity conditions then we are considering the derivative and other things. But if that is not satisfied then what? So, we will have another extension in that direction. So, in the next lecture we will be considering extensions to these things and then further applications of this.

That is all for today's lecture.
