Lecture – 51
Likelihood Ratio Tests- I

In the last few lectures, I have developed the theory of most powerful uniformly most powerful; uniformly most powerful unbiased tests. So, the basic building block of these tests was the Neyman and Pearson fundamental Lemma whose philosophy was that we fix level of significance, for a fixed level of significance you derive the most powerful uniformly most powerful or uniformly most powerful unbiased tests.

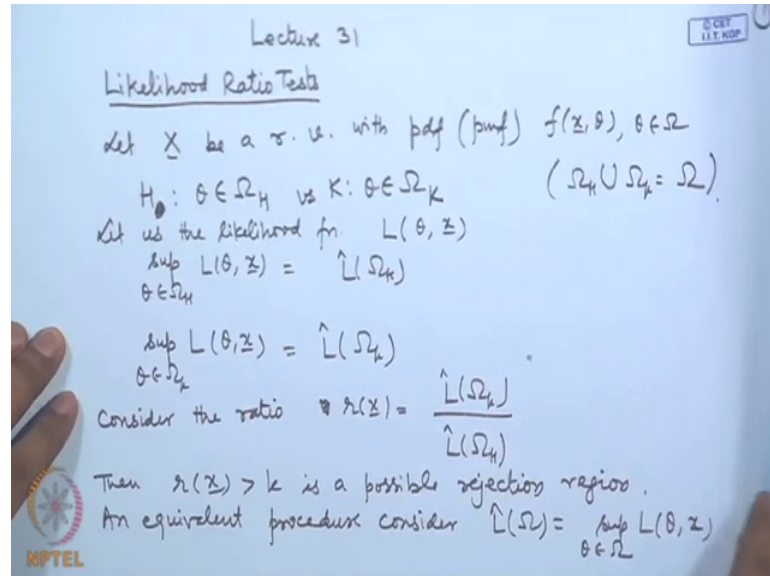

However, we have seen that in a wide variety of problems these type of tests are not applicable. For example, when we want to derive UMP tests then we are imposing a condition on the family of distributions that they should have monotone likelihood ratio property. Now there are large number of distributions which may not have monotone Likelihood Ratio property. Further when we develop that theory of unbiased UMP tests for hypothesis of that where the null hypothesis could be 1 sided or point null hypothesis or an interval, but the alternative hypothesis was 2 sided, in that case the UMP test was not available.

In fact, UMP unbiased test was derived, but it was for a 1 parameter exponential family. Later on when we have developed the general theory of UMP unbiased tests, we have considered multi parameter exponential families only and that too we should have the complete sufficient exact statistic. Now there can be many practical applications where these conditions will not be satisfied and therefore, we need certain other method for deriving the tests.

Now, as we have seen in the estimation problem one can restrict attention to the joint distribution which we term as the likelihood function. In the estimation problems we considered that value of the parameter to be the maximum likelihood estimator which maximize that likelihood function. Therefore, this maximization of the likelihood function is a heuristic thing; that means, on your own as a layman we think that we should consider the probable values are the most probable value for the likelihood

function. Now using this philosophy likelihood ratio tests are derived and let me introduce the theory of likelihood ratio test.

(Refer Slide Time: 03:11)

So, let X be a random vector with probability density function or probability mass function say $f(x, \theta)$; θ belonging to Ω . We want to test say H_0 versus K , we have introduced the notation H_0 for the null hypothesis and K for the alternative hypothesis when we were developing the UMP test, we had considered 4 types of hypothesis H_1 vs K_1 , H_2 vs K_2 , H_3 vs K_3 and H_4 vs K_4 .

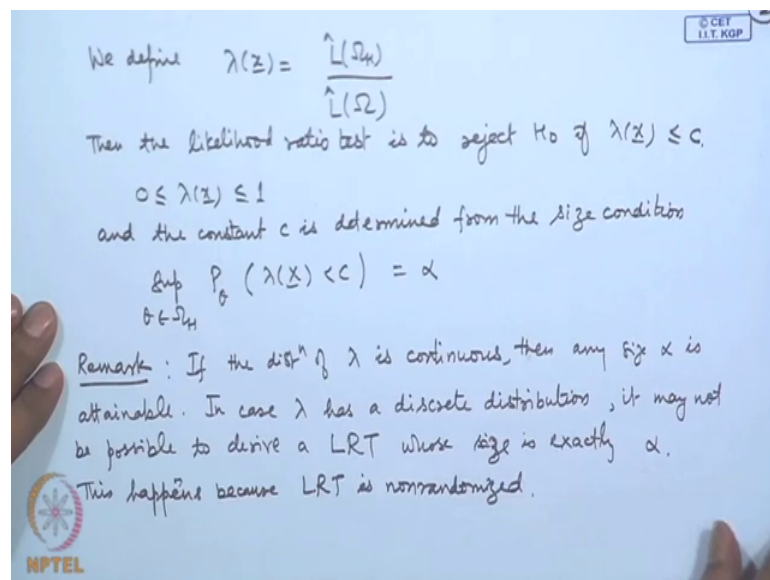

So, in general I will consider θ belonging to Ω_H versus θ belonging to Ω_K as the alternative hypothesis where $\Omega_H \cup \Omega_K = \Omega$. Now, we may consider say maximum of the likelihood function. So, we call it $L(\theta, x)$ that is nothing, but the joint distribution of the random variables under consideration, we consider the maximum value or the sup of $L(\theta, x)$, let me call it $\hat{L}(\Omega_H)$.

And we also consider the maximum of the likelihood function under Ω_K then a very natural procedure is to consider the ratio, let me call it $r(x)$ that is equal to $\hat{L}(\Omega_K)$ divided by $\hat{L}(\Omega_H)$. So, then $r(x) > k$ is a possible rejection region, what is the criteria for this?

Because if the alternative hypothesis is more likely to happen, then $L(\hat{\omega}_k)$ will have a higher value and if null hypothesis is more likely to happen, then $L(\hat{\omega}_H)$ will be higher value or bigger value. Therefore, the rejection region should be for the larger values of this ratio, acceptance region for lower values.

Now, this requires 2 maximizations and at least one of the maximizations could be more complicated we have seen the problems like 1 sided or 2 sided hypothesis testing problems. So, overall consideration of $L(\hat{\omega}_H)$ and $L(\hat{\omega}_k)$ may be slightly difficult and equivalent procedure considers say $L(\hat{\omega})$ that is the maximum of the likelihood function over the full parameter space.

(Refer Slide Time: 06:51)

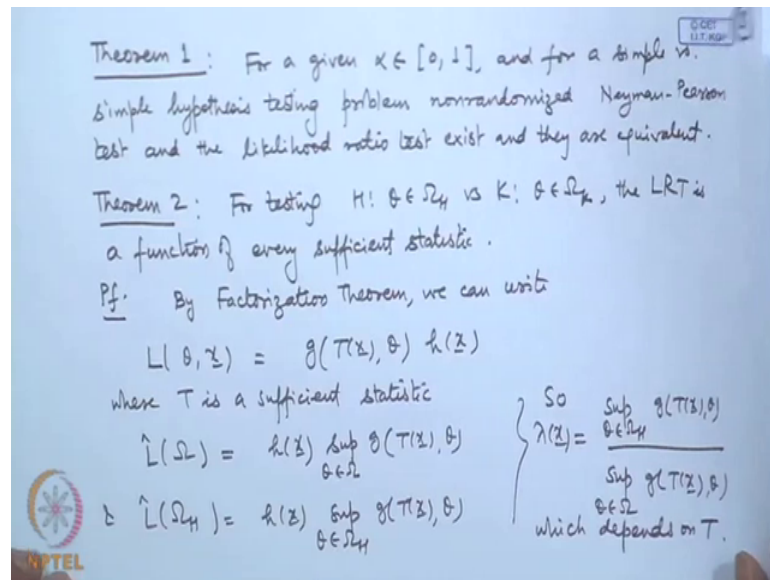

And we define the ratio $\lambda(x)$ is equal to $L(\hat{\omega}_H)$ by $L(\hat{\omega})$. Then the likelihood ratio test is to reject H_0 if $\lambda(x)$ is less than or equal to c and we will determine and of course, see this is maximization over the full parameter space. So, naturally you will have this thing between 0 and 1 and the constant c is determined from the size condition supremum of the probability of $\lambda(x) \leq c$ θ belonging to Ω_H is equal to α .

Now as a remark let me say that, if the distribution of λ is continuous, then any size α is attainable in case λ has a discrete distribution, it may not be possible to derive a likelihood ratio test whose size is exactly α .

However, this is happening because likelihood ratio test the way I am defining it is actually a non randomized test. This happens in the Neyman Pearson theory we were allowing the randomization, but in the likelihood ratio test randomization is not there. So, this happens because likelihood ratio test is non randomized.

(Refer Slide Time: 10:05)

We have the following equivalence result, let me call it theorem 1; for a given alpha belonging to 0 to 1 and for a simple versus, simple hypothesis distinct problem non randomized Neyman Pearson test and the likelihood ratio test exist and they are equivalent.

Because in the Neyman Pearson theory if you look at the simple versus simple you had f_1 by f_0 which is nothing, but the likelihood ratio corresponding to the null and alternative hypotheses as f_0 and f_1 . We have another result as we have seen in the maximum likelihood estimation because of the factorization theorem the likelihood function can be written as a product of a function which is free from the parameter and another term which is involved in the parameter.

So, when we take the ratio the term which is not having the parameter becomes gets cancelled out and therefore, you are getting only the sufficient statistic. Therefore, for testing say $H: \theta \in \Omega_H$ versus $K: \theta \in \Omega_K$, the likelihood ratio test is a function of every sufficient statistic. Proof is very simple by factorization theorem, we can write the likelihood function as $g(T(z), \theta) h(z)$, where

T is a sufficient statistic. So, $L(\hat{\omega})$ that will be equal to $h(x)$ into supremum of $g(T, x, \theta)$ where θ belongs to ω and $L(\hat{\omega})$ that is equal to $h(x)$ into supremum of $g(T, x, \theta)$; θ belonging to ω^c .

So, if I consider $\lambda(x)$ that will be simply supremum of θ belonging to ω^c of T, x, θ divided by supremum of θ belonging to ω of T, x, θ , which depends on T . Therefore, the likelihood ratio test it will depend only on the sufficient statistic. Now let me derive the likelihood ratio test for various problems for which we have derived the Neyman Pearson tests that is the UMP unbiased test etcetera. For similar problems let me derive the likelihood ratio test. So, let me start with say normal distributions.

LRT for parameters of a Normal Population

Let X_1, \dots, X_n be a random sample from $N(\mu, \sigma^2)$.

$\Omega = \{(\mu, \sigma^2) : -\infty < \mu < \infty, \sigma^2 > 0\}$

Let us consider testing for mean:

Case I: $H_0: \mu \leq 0, K_1: \mu > 0$

$\Omega_{H_0} = \{(\mu, \sigma^2) : -\infty < \mu \leq 0, \sigma^2 > 0\}$

$L(\mu, \sigma^2, x) = \prod_{i=1}^n f(x_i, \mu, \sigma^2) = \frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} \sum (x_i - \mu)^2}$

$\log L = -\frac{n}{2} \log \sigma^2 - \frac{n}{2} \log 2\pi - \frac{1}{2\sigma^2} \sum (x_i - \mu)^2$

NPTEL

So, likelihood ratio tests for parameters of a normal population. So, we have let X_1, X_2, \dots, X_n be a random sample, from say normal μ, σ^2 distribution. So, as before the full parameter space ω it is a set of all μ, σ^2 , such that μ is from minus infinity to infinity and σ^2 is positive, if I say σ^2 then I can write like that. Let me consider; let us consider testing for mean, note here that I am considering here full model; that means, both μ and σ^2 are unknown.

If you remember the Neyman Pearson theory I have considered various possibilities, initially when I tested for the mean I had assumed variance to be known and when I tested for variance I had assumed mean to be known. And then later on we have derived

the test when both are unknown and in the final analysis we got the uniformly most powerful unbiased tests for those situations. Now in the likelihood ratio test I am considering the problem, where both the parameters μ and σ^2 are unknown.

Now let us consider say the hypothesis of the nature that H_1 , that is $\mu \leq \mu_0$ against $\mu > \mu_0$. Now, without loss of generality I can take μ_0 to be 0. So, I can consider the hypothesis $\mu \leq 0$ against $\mu > 0$. Now we need to consider if we want to apply the likelihood ratio test, then I need to consider $L(\hat{\omega}_H)$ by $L(\hat{\omega})$ and what is $L(\hat{\omega}_H)$? $L(\hat{\omega}_H)$ is nothing, but the maximization of the likelihood function over the null hypothesis parameter space.

Similarly, $L(\hat{\omega})$ is the maximization of the likelihood function over the full parameter space. So, if we take care of these values then let us write down ω_H as written here, what is ω_H then? ω_H is the set of all those μ, σ^2 for which $\mu \leq 0$ and σ^2 is positive. So, note here this has become a subset of ω let us write down the likelihood function, here we have 2 parameters. So, this is a joint distribution of X_1, X_2, \dots, X_n . So, we have been writing this terms several times.

So, it is $(2\pi)^{-n/2} \sigma^{-n} \exp\left\{-\frac{1}{2\sigma^2} \sum_{i=1}^n x_i^2\right\}$. Now if we consider \log of L , then that is equal to $-\frac{n}{2} \log(2\pi) - \frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^n x_i^2$.

(Refer Slide Time: 18:36)

$$\frac{\partial \log L}{\partial \mu} = \frac{1}{\sigma^2} \sum (x_i - \mu) = \frac{n(\bar{x} - \mu)}{\sigma^2} < 0 \text{ if } \mu > \bar{x}$$

$$> 0 \text{ if } \mu < \bar{x}$$

So $\log L \uparrow$ for $\mu < \bar{x}$
 \downarrow for $\mu > \bar{x}$
 So maximum over μ is attained for $\mu = \bar{x}$ (on Ω)

$$\frac{\partial \log L}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (x_i - \mu)^2$$

$$= \frac{n}{2\sigma^4} \left[\frac{\sum (x_i - \mu)^2}{n} - \sigma^2 \right]$$

> 0 if $\sigma^2 < \frac{\sum (x_i - \mu)^2}{n}$
 < 0 if $\sigma^2 > \frac{\sum (x_i - \mu)^2}{n}$

So $\log L \uparrow$ for $\sigma^2 < \frac{\sum (x_i - \mu)^2}{n}$
 \downarrow for $\sigma^2 > \frac{\sum (x_i - \mu)^2}{n}$

If you look at the derivative del mu that is equal to sigma xi minus mu by sigma square that is equal to n x bar minus mu by sigma square. So, this is less than 0, if mu is greater than x bar it is greater than 0, if mu is equal to x bar. So, log L is increasing sorry this is mu less than x bar. So, log l is increasing for mu less than x bar it is decreasing for mu greater than x bar.

So, maximum over mu is attained for mu is equal to x bar, this is on omega. See we are firstly, considering the maximization over omega and then over omega H. So, and then if I consider derivative with respect to sigma squared then I will get minus n by 2 sigma square plus 1 by 2 sigma to the power 4 sigma xi minus mu square.

Now, once again we combine the terms I can write it as sigma xi minus mu square, I can take out 1 by 2 sigma to the power 4 maybe I can take out n also, so this divided by n minus sigma square. Once again you note here this is greater than 0 if sigma square is less than sigma xi minus mu square by n and it is less than 0 if sigma square is greater than sigma xi minus mu square by n. So, log L is increasing for sigma square less than sigma xi minus mu square by n and decreasing for sigma square greater than sigma xi minus mu square by n.

(Refer Slide Time: 21:15)

So maximum for σ^2 is attained when $\sigma^2 = \frac{1}{n} \sum (x_i - \mu)^2$.

So when we consider maximization of $L(\mu, \sigma^2, x)$ over Ω , we get at $\hat{\mu}_\Omega = \bar{x}$, $\hat{\sigma}_\Omega^2 = \frac{1}{n} \sum (x_i - \bar{x})^2$.

So $\hat{L}(\Omega) = \frac{1}{(2\pi \hat{\sigma}_\Omega^2)^{n/2}} e^{-\frac{n}{2}}$

$= \frac{1}{(2\pi \hat{\sigma}_\Omega^2)^{n/2}} e^{-\frac{n}{2}}$

In order to evaluate $\hat{L}(\Omega_H)$, we consider maximization of $L(\mu, \sigma^2, x)$ over Ω_H .

So, maximum for sigma square is attained when sigma square is equal to 1 by n sigma xi minus mu square. So, when we consider maximization of L over omega, we get at mu hat let me write mu hat omega is equal to x bar, sigma hat square omega is equal to 1 by n sigma xi minus x bar square.

So, L hat omega is nothing, but the value evaluated at this point, that is 1 by 2 pi sigma hat omega square to the power n by 2 e to the power minus 1 by 2 sigma omega hat square sigma xi minus x bar whole square i is equal to 1 to n by n sigma xi minus x bar whole square. So, if I substitute this term will get cancelled out and I will get it as simply 1 by 2 pi sigma omega hat square to the power n by 2 e to the power minus n by 2.

So, we have evaluated the maximization of the likelihood function over the full parameter space, in order to apply the likelihood ratio test I also need to consider in order to evaluate L hat omega H, we consider maximization of L mu sigma square x over omega H. Now, let us analyze over omega H.

(Refer Slide Time: 23:54)

minimum for σ^2 is obtained when $\sigma^2 = \frac{1}{n} \sum (x_i - \mu)^2$.

$$\frac{\partial \log L}{\partial \mu} = \frac{1}{\sigma^2} \sum (x_i - \mu) = \frac{n(\bar{x} - \mu)}{\sigma^2} \begin{cases} < 0 & \text{if } \mu > \bar{x} \\ > 0 & \text{if } \mu < \bar{x} \end{cases} \quad (1)$$

So $\log L \uparrow$ for $\mu < \bar{x}$
 \downarrow for $\mu > \bar{x}$
 So maximum over μ is obtained for $\mu = \bar{x}$ (on Ω)

$$\frac{\partial \log L}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (x_i - \mu)^2$$

$$= \frac{n}{2\sigma^4} \left[\frac{\sum (x_i - \mu)^2}{n} - \sigma^2 \right] \begin{cases} > 0 & \text{if } \sigma^2 < \frac{\sum (x_i - \mu)^2}{n} \\ < 0 & \text{if } \sigma^2 > \frac{\sum (x_i - \mu)^2}{n} \end{cases}$$

We have already looked at the derivatives here, so look at del log L by del mu, we have seen the behavior of it. So, let me give this some numbering here this is say 1 and this one is say 2.

(Refer Slide Time: 23:57)

$$\frac{\partial \log L}{\partial \mu} = \frac{1}{\sigma^2} \sum (x_i - \mu) = \frac{n(\bar{x} - \mu)}{\sigma^2} \begin{cases} < 0 & \text{if } \mu > \bar{x} \\ > 0 & \text{if } \mu < \bar{x} \end{cases} \quad (1)$$

So $\log L \uparrow$ for $\mu < \bar{x}$
 \downarrow for $\mu > \bar{x}$
 So maximum over μ is obtained for $\mu = \bar{x}$ (on Ω)

$$\frac{\partial \log L}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (x_i - \mu)^2$$

$$= \frac{n}{2\sigma^4} \left[\frac{\sum (x_i - \mu)^2}{n} - \sigma^2 \right] \begin{cases} > 0 & \text{if } \sigma^2 < \frac{\sum (x_i - \mu)^2}{n} \\ < 0 & \text{if } \sigma^2 > \frac{\sum (x_i - \mu)^2}{n} \end{cases} \quad (2)$$

So $\log L \uparrow$ for $\sigma^2 < \frac{\sum (x_i - \mu)^2}{n}$
 \downarrow for $\sigma^2 > \frac{\sum (x_i - \mu)^2}{n}$.

Because we will be using these expressions of del log L by del mu and del log L by del sigma square.

(Refer Slide Time: 24:18)

So, from 1, we have the behavior of $\log L$ as, so let me just draw. So, it is something like this is increasing up to \bar{x} , so I am treating it as a function of μ and this is function of μ . I am treating it as a function of, so as a function of μ it increases up to \bar{x} and thereafter it is decreasing. Now it will depend upon where what is the position of 0 because in the omega H we have to maximize over minus infinity less than μ less than or equal to 0 σ^2 greater than 0; that means, μ is less than or equal to 0. So, when we look at this let us look at there are 2 cases.

One case \bar{x} is less than 0, if \bar{x} is less than 0; that means, 0 is say here in that case 1 μ σ^2 $\log L$ will be maximized at \bar{x} . Now second case is \bar{x} is greater than 0, if \bar{x} is greater than 0; that means, the position of 0 is here, if the position of 0 is here this is the likelihood function, it is increasing up to 0 and we are only looking at this region, so the maximum value is attained at 0.

So, then $\log L$ μ σ^2 attains maximum at 0. So, what we are getting $\hat{\mu}_{ML}$ omega H it is equal to minimum of \bar{x} and 0, because it is \bar{x} if \bar{x} is less than 0 and it is 0 if 0 is less than \bar{x} . So, at 1 place we may put equality here.

(Refer Slide Time: 26:42)

We also look at max wrt σ^2 ;

$$\hat{\sigma}_{\Omega_H}^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \hat{\mu}_{\Omega_H})^2.$$

So

$$\hat{L}(\Omega_H) = \frac{1}{(\hat{\sigma}_{\Omega_H}^2 \cdot 2\pi)^{n/2}} e^{-\frac{1}{2\hat{\sigma}_{\Omega_H}^2} \sum (x_i - \hat{\mu}_{\Omega_H})^2}$$

$$= \frac{1}{(2\pi \hat{\sigma}_{\Omega_H}^2)^{n/2}} e^{-\frac{n}{2}}$$

The likelihood ratio test is to Reject H_1 if

$$\lambda(x) = \frac{\hat{L}(\Omega_H)}{\hat{L}(\Omega)} < c$$

Let us look at the maximization of we also look at max with respect to sigma square. Now when we look at the max with respect to sigma square, we have shown here that the max is occurring at sigma square is equal to sigma xi minus mu whole square by n that is a statement we gave here. For sigma square the max is occurring at sigma square is equal to this quantity. Now this mu I had substituted as mu hat, now in this case mu hat is modified.

So, accordingly sigma square will get modified and we get sigma omega H hat square that will become 1 by n sigma xi minus mu hat omega H square i is equal to 1 to n. So, L hat omega H that will be equal to 1 by sigma omega H hat square into 2 pi e to the power n by 2 e to the power minus 1 by 2 sigma omega H hat square sigma xi minus mu hat omega H square.

Once again if I substitute the value of sigma omega H hat square then I will get n by 2 here. So, this is equal to 1 by 2 pi sigma omega H hat square to the power n by 2 e to the power minus n by 2. So, the likelihood ratio test is to reject H_1 if lambda x that is equal to L hat omega H by L hat omega less than say some constant c.

(Refer Slide Time: 29:01)

This is equivalent to

$$\left(\frac{\prod_{i=1}^n \frac{\sigma_0^2}{\sigma_1^2} \left(\frac{\sigma_1^2}{\sigma_0^2} \right)^{n/2}}{\prod_{i=1}^n \frac{\sigma_1^2}{\sigma_0^2}} \right)^{n/2} < c$$

or

$$\frac{\prod_{i=1}^n \frac{\sigma_0^2}{\sigma_1^2}}{\prod_{i=1}^n \frac{\sigma_1^2}{\sigma_0^2}} < c_1 \Leftrightarrow \frac{\prod_{i=1}^n \frac{\sigma_0^2}{\sigma_1^2}}{\prod_{i=1}^n \frac{\sigma_1^2}{\sigma_0^2}} < c_1$$

If $\bar{x} < 0$, the LHS is 1. So we always accept H_1 and ($\alpha=0$)

When $\bar{x} > 0$, the test is

Reject H_1 if $\frac{\sum (x_i - \bar{x})^2}{\sum x_i^2} < c$

So, if I substitute the values of $L(\hat{\omega}_H)$ and $L(\hat{\omega})$, then $L(\hat{\omega})$ is this quantity and $L(\hat{\omega}_H)$ and $L(\hat{\omega})$ both are given here. So, the power minus n by 2 terms will get cancelled out and we will get the ratio as σ_0^2 divided by σ_1^2 to the power n by 2 less than c .

Now, I can take this power 2 by n here, so this is equivalent to σ_0^2 by σ_1^2 less than another constant say c_1 . Now let us substitute the values here this is 1 by n $\sum x_i - \bar{x}$ square divided by 1 by n $\sum x_i - \min(0, \bar{x})$ square, so this gets cancelled out less than c_1 . Now, if \bar{x} is less than 0 the left hand side is 1 , if this is 1 then basically what we have said likelihood ratio is always between 0 to 1 because in the numerator I have a smaller quantity than the denominator.

So, this is the extreme case, if it is an extreme case then we should always accept H_1 . So, we always accept H_1 and actually the probability α will become 0 . Now, when \bar{x} is greater than 0 , then here minimum will become 0 , so the test is reject H_1 if $\sum x_i - \bar{x}$ whole square divided by $\sum x_i^2$ is less than c_1 .

(Refer Slide Time: 31:25)

or when $\frac{\sum (x_i - \bar{x})^2}{\sum (x_i - \bar{x})^2 + n\bar{x}^2} < c_1$
 or $\frac{\sum (x_i - \bar{x})^2 + n\bar{x}^2}{\sum (x_i - \bar{x})^2} > c_2$
 or $\frac{n\bar{x}^2}{\sum (x_i - \bar{x})^2} > c_3$
 as $\bar{x} > 0$ or $\frac{\sqrt{n}\bar{x}}{\sqrt{\sum (x_i - \bar{x})^2}} > c_4$
 or $\frac{\sqrt{n}\bar{x}}{\sqrt{\frac{1}{n-1} \sum (x_i - \bar{x})^2}} > c_5$

Now c_5 is determined by
 $\sup_{\mu \leq 0} P\left(\frac{\sqrt{n}\bar{x}}{S} > c_5\right) = \alpha$
 $\frac{\sqrt{n}(\bar{x} - \mu)}{S} \sim t_{n-1}$
 $P\left(\frac{\sqrt{n}(\bar{x} - \mu)}{S} > \frac{\sqrt{n}(c_5 - \mu)}{S}\right)$
 is \uparrow in μ , so it will attain maximum at $\mu = 0$.

Or when sigma xi minus x bar square divided by sigma xi minus x bar square plus nx bar square less than c 1 or if I take the reciprocal greater than say c 2. So, I can write it as in n x bar square by sigma xi minus x bar whole square greater than say some c 3.

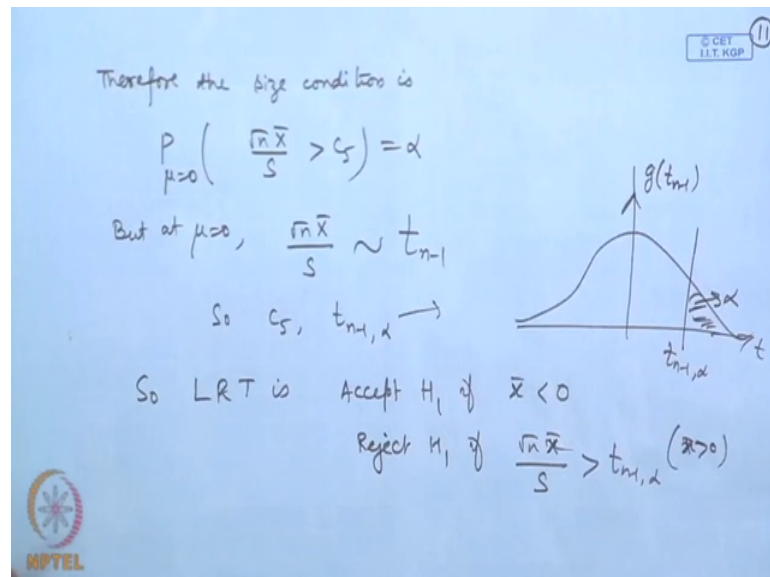

I can take the square root because x bar is positive as x bar is positive I can take the square root here this becomes the square root sigma xi minus x bar whole square greater than say c 4, I can adjust again and write. So, basically if you remember this is the test which we got in the UMP test also.

If I consider root n x bar divided by root 1 by n minus 1 sigma xi minus x bar whole square greater than say c 5. Now, this c 5 is determined by probability of root n x bar divided by S greater than c 5. If you remember the definition of S square that was 1 by n minus 1 sigma xi minus x bar whole square. So, n minus 1 S square by sigma square follows chi square distribution on n minus 1 degrees of freedom. So, when mu is equal to 0 this will follow T distribution on n minus 1 degrees of freedom.

So, here this is determined by supremum of this when mu is less than or equal to 0 equal to alpha, this supremum is over this. Now let us look at this thing root what is the distribution here? You are having root n x bar minus mu by S that follows T distribution on n minus 1 degrees of freedom ok. So, this probability then can be written as root n x bar minus mu by S greater than root n c 5 minus mu by S probability of this.

Now, if μ increases; if μ increases this limit will decrease the lower bound here because here it is coming as minus μ ok. So, if μ increases this will decrease, so this probability will increase, this probability is increasing in μ . So, it will attain maximum at μ is equal to 0.

(Refer Slide Time: 35:07)

Therefore, the size condition is probability of root n \bar{x} by S greater than c_5 at μ equal to 0 is equal to α , but at μ is equal to 0 root n \bar{x} by S this will follow T distribution on n minus 1 degrees of freedom. So, c_5 is nothing, but the upper 100 α percent point of the T distribution on n minus 1 degrees of freedom. If this is the curve of T distribution on n minus 1 degrees of freedom then on the side you have T, then this probably should be α . So, likelihood ratio test is accept H_0 if that is always accept H_0 if \bar{x} is less than 0 and reject H_0 if $\frac{\sqrt{n}\bar{x}}{S}$ is greater than $t_{n-1, \alpha}$ for \bar{x} positive.

So, there is a slight modification from the UMP test and UMP unbiased test for the situation we have derived if you remember in the lecture which I gave earlier.

(Refer Slide Time: 36:56)

distⁿ of W and T are independent when $\mu=0$.

by Thm 3, UMP unbiased test for H_1 vs K_1 is

Reject H_0 if $W \geq c$

$$W = \frac{\bar{X}}{\sqrt{\sum (x_i - \bar{x})^2}}$$

$\bar{X} \sim N(0, \sigma^2/n)$ ($\mu=0$)

$\frac{\sqrt{n}\bar{X}}{\sigma} \sim N(0,1)$

$\frac{\sum (x_i - \bar{x})^2}{\sigma^2} \sim \chi_{n-1}^2$

$\sqrt{n(n-1)} W = S = \frac{\sqrt{n}\bar{X}/\sigma}{\sqrt{\sum (x_i - \bar{x})^2 / \sigma^2 (n-1)}} \sim t_{n-1}$

When $\mu=0$, $S \sim t_{n-1}$

$W \geq c \Leftrightarrow S \geq k$, $P(S \geq k) = \alpha$

$\mu=0 \downarrow t_{n-1, \alpha}$

The test that we derived here root n x bar; root n x bar by sigma xi minus x bar whole square by n minus 1 square root. So, the test was in the terms of this. So, in many situations the likelihood ratio test yield the similar test as the in the Nyman Pearson theory; that means, they are also the UMP unbiased tests and in many situation of 1 parameter they may be UMP tests also.

However, we have seen that sometimes it may not happen like that and in that case we need certain asymptotic properties fortunately for the likelihood ratio test the asymptotic properties do hold; that means, asymptotic distribution of the test S statistic is nice it becomes actually the chi square.
