Lecture - 07
Finding Estimators – I

In the previous two lectures, I have discussed certain desirable properties for Estimators; however still we are not clear, how to derive estimators for various kind of parameters. It may be one thing to say that we can estimate a population mean by a sample mean, a population variance by sample variance or a population range by sample range, but many a times we are having more complicated situations.

And moreover as we have already seen such as uniform distribution or an exponential distribution that we may have several estimators, maybe one is based on the mean, another is based on say order statistics, etcetera. So, there must be some procedures or methodology by which we should be able to derive the estimators.

(Refer Slide Time: 01:19)

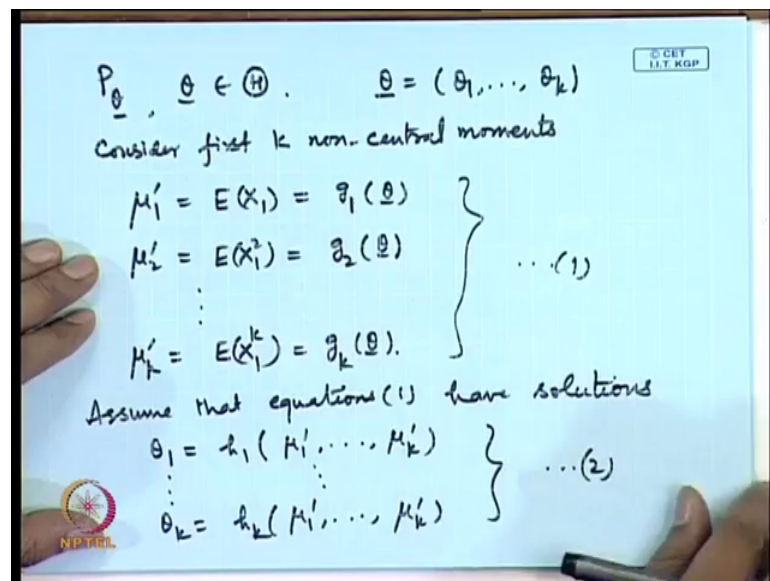

So, some of the well known methods which are used are the method of moments, the method of least squares, the method of minimum chi square, then maximum likelihood estimation and then there are certain new procedure such as Bayes estimation, minimax estimation. The last two procedures which I have mentioned, they are based on decision theoretic concepts and we may not be able to cover much of this in this particular course.

Historically, the method of moments seems to be the oldest one introduced by Karl Pearson.

So, let me start from here, the method of moments. Let us consider that we have a random sample, X_1, X_2, \dots, X_n be a random sample from a population with say distribution, which is identified as say P_θ , θ belongs to Θ .

(Refer Slide Time: 03:13)

So, here in general I am considering θ to be a vector parameter that means, θ may have component say $\theta_1, \theta_2, \dots, \theta_k$. As we have already talked about for example, if you consider a normal distribution, usually it is characterized by two parameters μ and σ^2 . So, in that case θ is $\mu \sigma^2$.

Similarly, if we consider a Poisson distribution, it is characterized by a single parameter say λ . We may have a Weibull distribution, we may have a gamma distribution. So, these are variously described by 2, 3 or 5 parameters, etcetera. So, in general if we have k dimension parameter, we consider k moments.

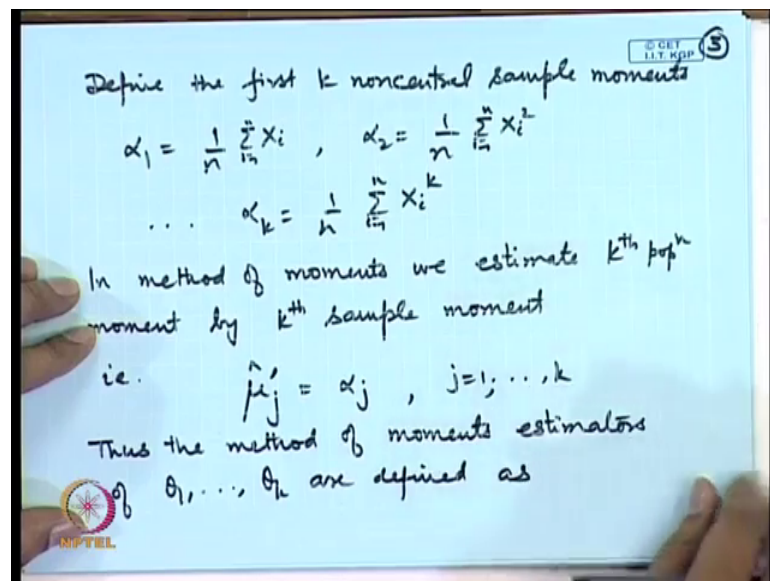

So, let us consider first k non-central moments that means, we calculate say μ'_1 , which is expectation of say X_1 that is now all of these moments, they are going to be functions of the parameter. So, let us call this function as a g_1 of θ . Similarly, μ'_2 that is the second moment of the distribution, this will be another function of θ

let us call it μ_2 and so on. Let us write say μ_k is equal to expectation of X^k to the power k that is μ_k of θ .

Now, we assume that this k equations. So, each of this is a function of $\theta_1, \theta_2, \dots, \theta_k$. So, we assume that this equations, they have solutions assume that the system of equations have solutions. Now, the solutions will be in the form that means, I am saying θ_1 is h_1 of say μ_1, μ_2, μ_k and so on.

θ_k is h_k of μ_1, μ_2, μ_k ; let us call it, 2. In method of moments, what we do in place of this μ_1, μ_2, μ_k , which are the first k non-center moments of the population, we substitute these by the corresponding sample moments.

(Refer Slide Time: 06:14)

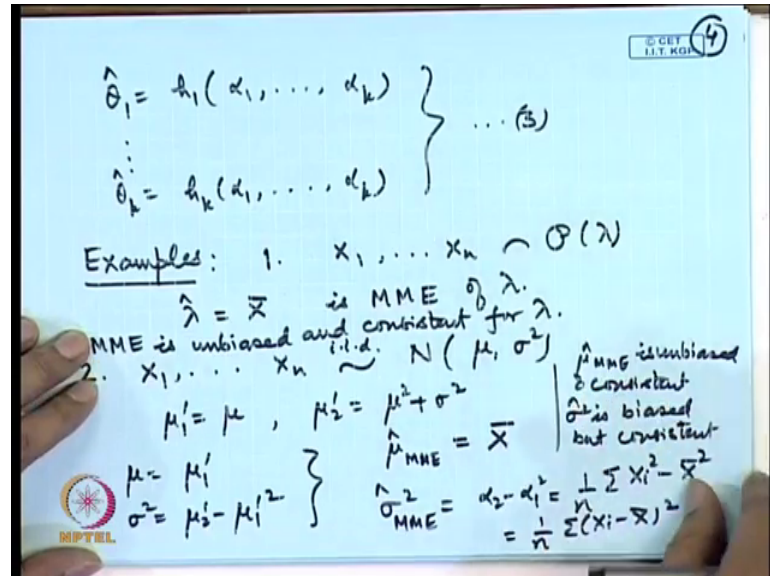

So, let us defines say sample moments as define the first k non-central sample moments that means, let me define say α_1 is equal to $\frac{1}{n} \sum X_i$, α_2 is say $\frac{1}{n} \sum X_i^2$, i is equal to 1 to n . In general, so α_k is equal to $\frac{1}{n} \sum X_i^k$ to the power k , i is equal to 1 to n .

In method of moments, we estimate k th population moment by k th sample moment that is I am writing that $\hat{\mu}_j = \alpha_j$, for j is equal to 1 to k . So, these values we substitute here, thus the method of moments estimators of $\theta_1, \theta_2, \dots, \theta_k$

2, theta k are defined as; theta 1 hat is equal to h 1 of alpha 1, alpha 2, alpha k and so on. Theta k hat is equal to h k of alpha 1, alpha 2, alpha k.

(Refer Slide Time: 08:08)

Now, the question may come that if we are having the solutions to this equations; if the solutions to this equations are obtainable in the explicit form, then only we can write down the solution for the method of moments. There may be some cases, where you may have say two parameters or three parameters, but two or three equations may not lead to the solutions in that case we may take extra moments here.

So, let me start with certain examples here, the simplest one for example I may consider say X_1, X_2, X_n follow a Poisson lambda distribution. Now, this is the one parameter case, so I need to take up only the first moment. Now, we know that the first moment of the Poisson distribution is lambda and the first sample moment is \bar{X} . So, lambda hat as equal to \bar{X} . So, this is the method of moment estimator of lambda.

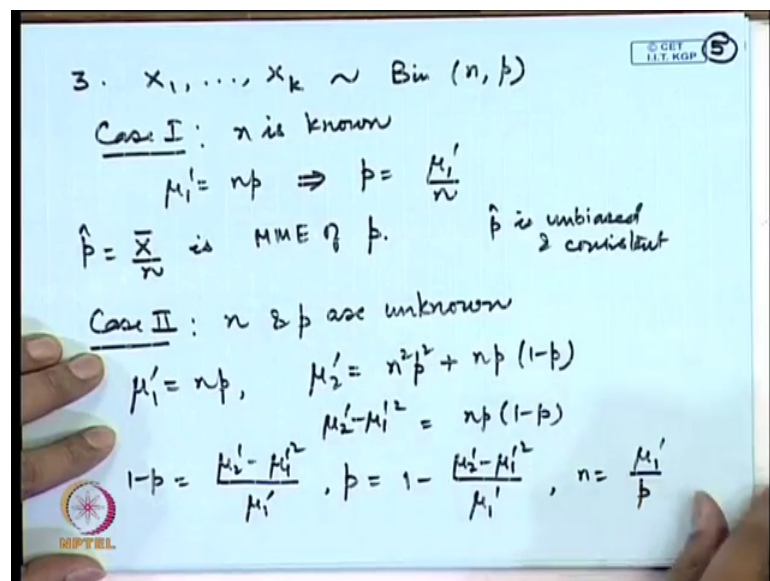

Let us take, say X_1, X_2, X_n following normal μ sigma square distribution, where both μ and sigma are parameters here, unknown parameters. Let us take here, μ_1' in normal distribution the means is μ ; μ_2' is equal to the second moment is $\mu^2 + \sigma^2$.

So, if you solve this we get μ is equal to μ_1' and sigma square is equal to $\mu_2' - \mu_1'^2$. So, this is the system which is equivalent to this

system that theta i is are written in terms of the mu i primes. So, now we substitute alpha 1 for mu 1 prime and alpha 2 for mu 2 prime. So, the method of moments estimators for mu hat mu let me call it MME, that is denoting the Method of Moments Estimator of mu; it is simply X bar that is alpha 1.

And for sigma square, it is equal to alpha 2 minus alpha 1 a square. Let us see what is the value of this it is 1 by n sigma X i square minus X bar square, which I can write as 1 by n sigma X i minus X bar whole square. Notice here, in the previous classes when I was discussing unbiased estimation, I derived the unbiased estimator of sigma square as s square that was 1 by n minus 1 sigma X minus X bar square. So, there is a clear cut case of comparison between the method of moment's estimator and an unbiased estimator, in this particular problem.

(Refer Slide Time: 11:47)

Let us take, say X 1, X 2, X k following a binomial distribution with parameters n and p. Quite difficult situations in binomial distribution deal with the situations, where n is known. So, if we have n is known, then parameter is p here. And if I considered the first moment here, first moment of the binomial distribution is n p. So, this is to be estimated by alpha 1 that means, X bar is an estimate of n p.

So, if you want write down the solution p is equal to mu 1 prime by n. So, we get here p hat is equal to X bar by n, so this is method of moments estimator of p. Since here, only one parameter was there be considered only one equation.

Now, let us take the more general case, where n and p both are unknown. When both are unknown, then we will have to take up the first two moments. So, μ_1' is equal to np , and μ_2' is equal to $np^2 + np(1-p)$. In the binomial distribution, the second moment is equal to this value here.

Now, we can solve this equation actually if we take up say $\mu_2' - \mu_1'^2$, I get $np(1-p)$. So, if I divide this equation by this, I get $1-p$ is equal to $\mu_2' - \mu_1'^2$ by μ_1' . So, the solution for p as come and if I substitute that value of p here, I get the value of n . So, I get p is equal to $1 - \frac{\mu_2' - \mu_1'^2}{\mu_1'}$ and n is equal to $\frac{\mu_1'}{p}$. So, now by substituting α_1 and α_2 for μ_1' and μ_2' , I get the method of moment's estimator for n and p .

(Refer Slide Time: 14:37)

The image shows handwritten mathematical derivations on a whiteboard. The first equation is
$$\hat{p}_{MME} = 1 - \frac{\alpha_2 - \alpha_1^2}{\alpha_1} = \frac{\bar{X} - \frac{1}{k} \sum_{i=1}^k (x_i - \bar{X})^2}{\bar{X}}$$
 The second equation is
$$\hat{n}_{MME} = \frac{\bar{X}^2}{\bar{X} - \frac{1}{k} \sum_{i=1}^k (x_i - \bar{X})^2}$$
 Below these, there are notes: $\bar{X} \xrightarrow{p} np$, $\frac{1}{k} \sum x_i^2 \rightarrow n^2 p^2 + np(1-p)$ However $\hat{n} \xrightarrow{p} n$ eg. $k=2, x_1=2, x_2=6, \bar{x}=4$ $\frac{1}{k} \sum (x_i - \bar{x})^2 = 4$

So, let us look at this value here. We get \hat{p}_{MME} as $1 - \frac{\alpha_2 - \alpha_1^2}{\alpha_1}$. Here, α_1 is \bar{X} and α_1^2 is $1/n \sum X_i^2$. So, if you substitute those values, this turns out to be $\bar{X} - \frac{1}{n} \sum (X_i - \bar{X})^2$ by \bar{X} . In this case it is $1 - \frac{1}{k} \sum (x_i - \bar{x})^2$ by \bar{x} .

And n is estimated by \bar{X}^2 divided by $\bar{X} - \frac{1}{k} \sum (X_i - \bar{X})^2$. Notice here, when n was known then the estimate for p was simply \bar{X} by n , whereas now you can see it has change quite drastically here.

In the context of these excises, let us also see some other properties which we had earlier for example, unbiasedness. Now, you see in the Poisson distribution case expectation of \bar{X} is equal to λ . So, the method of moment's estimator is actually unbiased. It will also be consistent if we apply the weak law of large numbers as we have already seen that if the first moment exist, the sample mean is always a consistent estimator for the population mean.

So, in this case MME is unbiased and consistent for λ . Let us take up the second one; normal distribution is example, here if we are looking at \bar{X} , when \bar{X} is unbiased for μ and also it is consistent. However, if you look at the estimator for σ^2 , you can notice here that it is not unbiased; however, it will remain consistent, because it is actually $\frac{1}{n-1} \sum X_i^2$. So, since $\sum X_i^2$ was consistent and $\frac{1}{n-1}$ converges to 1, this also converges to 1.

Therefore, here you are having that $\hat{\mu}$ MME is unbiased and consistent, however $\hat{\sigma}^2$ is biased, but consistent. So, this brings us to important property that the method of moments estimators need not always be unbiased. Now, in these two excises they are consistent.

So, again the question arises whether they will be consistent always, let us take up the next case. Here, \bar{X} by n this is unbiased as well as consistent so, \hat{p} is unbiased and consistent. Let us take a second case when both the parameters, where unknown. Here if you see, since \bar{X} was unbiased for p ; so this cannot be unbiased, because this is quite different.

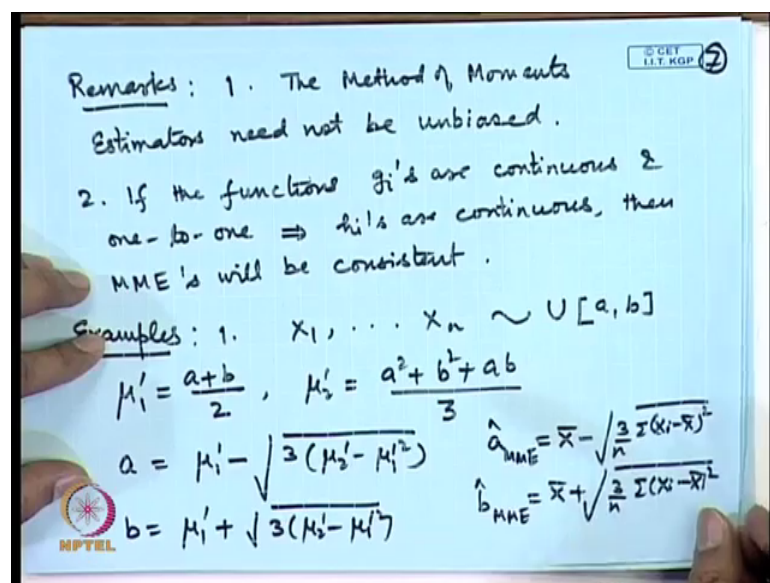

If you take up the limits here, so we are having \bar{X} converges to np in probability. We are having $\frac{1}{n} \sum X_i^2$ that is α^2 , this converges to the second moment that is $n p^2 + n p (1-p)$. So, both of these are convergent in probability. Now, let us look at this quantity in the denominator you are having $\bar{X} - p$ this quantity. So, if you look at the limit here, this going to np and this going to the variance term that is $n p (1-p)$ here.

So, this does not converge actually, because for convergence in probability we are established one property that is the invariance property, but the invariance properties only for the continuous functions. Here this not a continuous functions, because the denominator may become 0 however, \hat{p} does not converge to p in probability. We

may take one illustration here, you may take say k equal to 2; let me take observation say X_1 is equal 2, X_2 is equal say 6. So, \bar{X} is equal to 4 and if I calculate one by $k \sum (X_i - \bar{X})^2$ that is also equal to 4.

So, this denominator actually becomes 0 and the probability of this is positive because I am taking it to be actual observations here. Therefore, we conclude here that the method of moments estimator need not be consistent also so, this is the method. Sometimes the properties of unbiasedness and consistency hold, sometimes they do not hold.

(Refer Slide Time: 20:23)

So, let me give it comments here. The method of moments estimators need not be unbiased. If the functions say g_i 's are continuous and one-to-one; in that case inverse functions will exist and they will be continuous h_i 's are continuous, then MME's will be consistent that means, you are not always consistent, but under certain conditions they will be consistent.

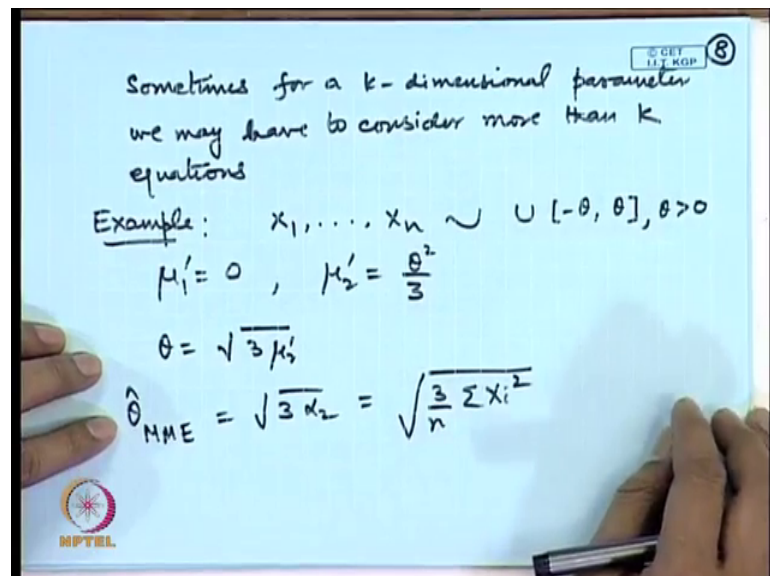

Let us take up another case let us take say X_1, X_2, \dots, X_n a random sample from a uniform distribution say I am the interval a to b . Again you may have different conditions for example, it maybe one parameter situation; that means, a may be known, or b may be known, or both maybe unknown. So, I will consider the case when both a and b are unknown, so that means, we have two parameters. So, we write down the first two moments the mean is $a + b$ by 2 and the second moment is $a^2 + b^2 + ab$ by 3.

So, we need to solve this. If you solve this we get a is equal to μ_1 prime minus square root $3 \mu_2$ prime minus μ_1 prime square. And b as μ_1 prime plus square root 3 times μ_2 prime minus μ_1 prime square. So, these are the basically equations in two unknowns and they are non-linear equations. However, one can solve it by making use of certain elementary relation such as a minus b is equal to a square root of a plus b whole square minus $4 a b$.

So, I am assuming since the interval is from a to b , so I am taking a to be less than b . So, I am taking minus value here and plus value here. So, if we substitute the α_1 and α_2 here, then the method of moments estimator turn out to be \bar{X} minus a square root 3 by n sigma X_i minus \bar{X} square. And \hat{b} MME as \bar{X} plus a square root 3 by n sigma X_i minus \bar{X} square.

In this particular case, we may see that these estimators may be consistent. Now, the reason for that is that α_1 is consistent for μ_1 prime; and α_2 is consistent for this. And this is continuous function here and that is the inverse functions that we have considered they are continuous. Therefore this will be consistent. However, they are not unbiased.

(Refer Slide Time: 24:52)

I mentioned that if I am having a k -dimensional parameter then we may usually considered k equations. So, why usually, because sometimes the k equations may not give us the desirable result. Let us take a very simple example sometimes for a k -

dimensional parameter we may have to consider more than k equations. So, let us take an example for this situation say X_1, X_2, X_n follow a uniform distribution on the interval say minus theta to theta, where theta is a positive number.

Now, in this case let us see the first moment μ_1' is actually 0. So, this does not give any information about theta and therefore, how to estimate. So, a natural thing is to consider the second moment here. The second moment here turns out to be if we substitute in the previous formula of this, you will get theta square by 3, because a is minus theta and b is plus theta. So, if I substitute here, I will get theta square plus theta square minus theta square by 3, so that is theta square by 3. So, a solution to this is equal to square root of 3 μ_2' .

So, I may take the method of moments estimator as a square root 3 alpha 2 that is square root 3 by n sigma X_i square. So, here since the first moment did not give us any solution for theta, I am using second moment. I end up the section with two more examples; one for a two parameter gamma distribution, and one for a two parameter beta distribution.

(Refer Slide Time: 27:14)

$X_1, \dots, X_n \sim \text{Gamma}(p, \lambda)$
 $f(x) = \frac{\lambda^p}{\Gamma(p)} e^{-\lambda x} x^{p-1}, x > 0$
 $\mu_1' = \frac{p}{\lambda}, \quad \mu_2' = \frac{p(p+1)}{\lambda^2}$
 $p = \frac{\mu_2'^2}{\mu_2' - \mu_1'^2}, \quad \lambda = \frac{\mu_1'}{\mu_2' - \mu_1'^2}$
 $\hat{p}_{\text{HME}} = \frac{\bar{x}^2}{\frac{1}{n} \sum (x_i - \bar{x})^2}, \quad \hat{\lambda}_{\text{HME}} = \frac{\bar{x}}{\frac{1}{n} \sum (x_i - \bar{x})^2}$
 These are consistent but not biased.

Let us take say X_1, X_2, X_n following a gamma distribution with parameter say p and lambda. So, here lambda is corresponding to the rate of the corresponding Poisson process, that means, I am taking the density function is equal to lambda to the power p by gamma p e to the power minus lambda x x to the power p minus 1, x is greater than 0.

Now, in this distribution the first moment is μ_1 by λ and the second moment is equal to $\mu_1^2 + \mu_2 - \mu_1^2$ by λ^2 . So, quite easily we can solve this. The solution is in the form μ_1 is equal to μ_1^2 by $\mu_2 - \mu_1^2$ and λ is equal to μ_1 by $\mu_2 - \mu_1^2$. So, the method of moments estimators are easily obtained as \bar{X}^2 divided by $\mu_2 - \mu_1^2$ minus \bar{X} and λ MME is equal to \bar{X} divided by $\mu_2 - \mu_1^2$ minus \bar{X} . One can easily check that these are consistent, but not unbiased.

So, generally the method of moment estimators will be consistent, but usually they will not be unbiased. In fact, the typical situations where they will be unbiased is only when you are having the first moment only. So, in that case, the sample mean is unbiased for the population mean and therefore, unbiasedness will be satisfied.

(Refer Slide Time: 29:28)

The image shows a handwritten derivation on a whiteboard for the Beta distribution. It starts with the definition of the distribution: $X_1, \dots, X_n \sim \text{Beta}(\alpha, \beta)$. The probability density function is given as $f(x) = \frac{1}{B(\alpha, \beta)} x^{\alpha-1} (1-x)^{\beta-1}$, where $0 < x < 1$ and $\alpha, \beta > 0$. The first two moments are calculated: $M_1' = \frac{\alpha}{\alpha + \beta}$ and $M_2' = \frac{\alpha(\alpha+1)}{(\alpha+\beta)(\alpha+\beta+1)}$. These are then used to solve for the parameters: $\alpha = \frac{M_1'(M_1' - M_2')}{(M_2' - M_1'^2)}$ and $\beta = \frac{(1 - M_1')(M_1' - M_2')}{(M_2' - M_1'^2)}$. The corresponding method of moments estimators are $\hat{\alpha}_{MME} = \frac{\bar{X}(\bar{X} - \frac{1}{n} \sum X_i^2)}{\frac{1}{n} \sum (X_i - \bar{X})^2}$ and $\hat{\beta}_{MME} = \frac{(1 - \bar{X})(\bar{X} - \frac{1}{n} \sum X_i^2)}{\frac{1}{n} \sum (X_i - \bar{X})^2}$. A note at the bottom states that $\hat{\alpha}$ and $\hat{\beta}$ are consistent but biased.

Similarly, let us take up say beta distribution say with parameters alpha and beta, that means, I am considering the density function as equal to $\frac{1}{B(\alpha, \beta)} x^{\alpha-1} (1-x)^{\beta-1}$, where x is between 0 and 1. And alpha and beta both are unknown positive parameters. The first two moments of a beta distribution are $\frac{\alpha}{\alpha + \beta}$ and $\frac{\alpha(\alpha+1)}{(\alpha+\beta)(\alpha+\beta+1)}$. So, we can solve these equations by firstly, dividing and then subtracting by 1 etcetera.

So, the form of a solution is that α is equal to μ_1 prime into μ_1 prime minus μ_2 prime divided by μ_2 prime minus μ_1 prime square and β is equal to $1 - \mu_1$ prime μ_1 prime minus μ_2 prime divided by μ_2 prime minus μ_1 prime square. So, if you substitute μ_1 prime as α_1 and μ_2 prime as α_2 , we get the method of moments estimator as \bar{X} into well this is $\bar{X} - 1$ by $n \sum X_i^2$ divided by $1 - \bar{X}$ by $n \sum X_i - \bar{X}^2$. And similarly $\hat{\beta}_{MME}$ is equal to $1 - \bar{X}$ into the same term here that is $\bar{X} - 1$ by $n \sum X_i^2$ divided by $1 - \bar{X}$ by $n \sum X_i - \bar{X}^2$.

In this case also, if we look at this thing these estimators are consistent, but not unbiased. So, this $\hat{\alpha}$ and $\hat{\beta}$ MME's they are consistent, but biased. Consistency is obvious because these things have turned out to be a to be continuous functions in fact, the denominator is always positive because μ_2 prime minus μ_1 prime square is actually the population variance.

And if you look at this function, so from here because of the basic weak law of large numbers \bar{X} converges to μ_1 prime in probability and $\sum X_i^2$ converges to μ_2 prime in probability. So, if you substitute these things here these things also remain consistent; however, they are not unbiased. In fact, later on when we discuss the theory of finding out unbiased estimators we will see what will be the actually corresponding unbiased estimators. So, today's class I end up at this point.
