Lecture - 20
Regular Singular Points-V

Hello friends, welcome to this lecture. In this lecture we continue our decision of regular singular point and if you recall in previous lecture we have discussed the case when the roots of the indicial equations differ by an integer and as an example we have taken the Bessel's equation of order 1/2 and we have seen that the equation is $t^2 y'' + t y' + (t^2 - 1/4) y = 0$.

So this is a Bessel equation of order 1/2 and we have already checked that here $t = 0$ is a regular singular point and we have also seen that the roots of the indicial equation is given by $r_1 = 1/2$ and $r_2 = -1/2$ and here we can say that $r_1 - r_2 = 1$.

(Refer Slide Time: 01:09)

$t^2 y'' + t y' + (t^2 - 1/4)y = 0$

$r_1 = 1/2 \quad r_2 = -1/2 \quad r_1 - r_2 = 1$

$a_{2n}(\frac{1}{2}) = \frac{(-1)^n}{2^{2n} n!}$

$F(r) = r^2 - 1/4$

$\checkmark F(n+r)a_n = 0$

$\Rightarrow [(n+r)^2 - 1/4]a_n = 0$

$r_2 = -1/2$

$0 a_1 = 0$

$a_1 = 0$

$\checkmark F(n+r)a_n = - \sum_{k=0}^{n-1} [(k+r)p_{n-k} + q_{n-k}] a_k$

$r_1 = 1/2$

$r_1 - r_2 = 1 = n_0 \Rightarrow 1$

$\frac{F(n+r_1)a_n}{0 - r_1} = - \sum_{k=0}^{n-1} [(k+r_1)p_{n-k} + q_{n-k}] a_k$

So it means that this case was in the category when the roots of the indicial equation differ by an integer and we also have calculated the coefficient corresponding to $r_1 = 1/2$ that is $a_{2n} = (-1)^n / 2^{2n} n!$ and here please note down that your indicial equation is given as $f(r) = r^2 - 1/4$ by which we have calculated the roots of the indicial equation that is $1/2$ and $-1/2$.

And we have also seen that if you look at the coefficient of t to the power $n + r$ in general theory we have already seen that f of $n + r$ $a_n = -k = 0, 2n-1 k + r P_n - k + q_n - k * a_k$. So here we have seen that if for some let us take r_2 as r_1 is bigger than r_2 and if you take the case corresponding to r_2 and that $r_1 - r_2$ is differed by some integer.

Let us say n_0 then this $n = n_0$ this is what, f of $n_0 + r_2$ $a_{n_0} = - \sum_{k=0}^{n_0-1} k + r P_{n_0-k} + q_{n_0-k} a_k$. Now here we already know that this $n_0 + r_2$ is r_1 and r_1 is the root of this (\cdot) (03:07) f of r so it means that this is going to be 0. So $a_{n_0}, 0 * a_{n_0} =$ this quantity. Now if this quantity is nonzero then we do not have any possibility to find out this a_{n_0} .

And hence we can say that we do not have any series solution of the form of Frobenius, but if this part is 0, if the righthand part is 0 then we can take any value of this a_{n_0} and in particular we take value of $a_{n_0} = 0$ and find out the other solution. So in this particular case your n_0 is basically 1. So $a_{n_0} = 1$. So here we look at the corresponding equation for this, the corresponding equation is f of $1 + r$ $a_1 = 0$.

So here it is quite easy to see that righthand side is already 0 so this righthand side is already 0 and if you look at the values of f of $1 + r$ that is $1 + r$ whole square $- 1/4 a_1 = 0$, now if you put r_2 as $-1/2$ then it is what, it is automatically 0, so it is 0 $a_1 = 0$. So it is in this particular problem this righthand side is already so. So this righthand side is already 0 in this particular example.

So here I can take value of a_1 as any value in particular I am taking the value of a_1 as 0. So it means that here we have the second series solution in the form of Frobenius form.

(Refer Slide Time: 04:49)

(Case 2). $r_2 = -\frac{1}{2}$ and set $a_0 = 1$. Equation (ii) is automatically satisfied, regardless the value of a_1 . We will set $a_1 = 0$. The recurrence relation (iii) becomes

$$a_n = \frac{-a_{n-2}}{(n - \frac{1}{2})^2 - \frac{1}{4}} = \frac{-a_{n-2}}{n(n-1)}, n \geq 2. \quad (13)$$

Since $a_1 = 0$ so by (13) we have $a_3 = a_5 = a_7 = \dots = 0$.
The even coefficient are given by

$$a_2 = \frac{-a_0}{2 \cdot 1} = -\frac{1}{2!}$$

$$a_4 = \frac{-a_2}{4 \cdot 3} = \frac{1}{4!}$$

and so on.

So let us continue our study, so here we take $r_2 = -1/2$ and we set $a_2 = 1$ and we say that equation 2 is automatically satisfied and you can take any value of a_1 and we will set $a_1 = 0$. If we take any nonzero value, then this I am leaving it to you that if you take a_1 as any nonzero value let us say that $a_1 = 1$ for example or $a_1 = \alpha$ if you take it and then you do all these calculations.

And at the end you will see that y_2 , the second solution which we are trying to find out corresponding to $r_2 = -1/2$ will contain a part of y_1 so that I am leaving it to you. So here now let us find out the solution corresponding to $r_2 = -1/2$ and here we have seen that here the problem which we are discussing is not occurring because here the righthand side is already 0.

So I can choose any value of a_1 and we have taken $a_1 = 0$ and since $a_1 = 0$ and by the recurrence relation we can simply say that all the odd terms are 0. Look at the recurrence relation $a_n + -a_{n-2}/n-1/2$ whole square $-1/4$ and we can simplify a square – b square and we can write $n-1/2 + 1/2$ that is n , $n-1/2-1/2$ that is $n-1$. So we can write a_n as $-a_{n-2}/n * n-1$ that is for $r_2 = -1/2$.

So we can calculate a_2 as $-a_0$ upon $2 * 1$ and a_0 is 1 so it is -1 upon factorial 2, a_4 as $-a_2$ upon $4 \cdot 3$, so a_2 is we have already calculated this, so a_4 is 1 upon factorial 4 and so on.

(Refer Slide Time: 06:41)

We can prove by induction that

$$a_{2n} = \frac{(-1)^n}{(2n)!}$$

So we can calculate that $a_{2n} = -1$ to the power n upon 2 to the power factorial $2n$. So we can say that by induction we can say that $a_{2n} = -1$ to the power n /factorial $2n$.

(Refer Slide Time: 06:50)

and in the general

$$a_{2n} = \frac{(-1)^n}{(2n)!}$$

Hence

$$y_2(t) = \frac{t^{\frac{1}{2}}}{t} \left(1 - \frac{t^2}{2!} + \frac{t^4}{4!} - \frac{t^6}{6!} \dots \right)$$

$$= \frac{1}{\sqrt{t}} \cos t.$$

is second solution of (10).

Handwritten notes:

$$y_1(t) = c_1 \frac{1}{\sqrt{t}} \sin t + c_2 \frac{1}{\sqrt{t}} \cos t$$

$$y_2(t) = t^{\gamma_2} \sum_{n=0}^{\infty} a_n t^n$$

$$\gamma_2 = -\frac{1}{2} \quad a_{2n} = \frac{(-1)^n}{(2n)!}$$

$$y_2(t) = \frac{1}{\sqrt{t}} \left(1 - \frac{t^2}{2!} + \frac{t^4}{4!} - \frac{t^6}{6!} + \dots \right)$$

Additional note: $a_{2n+1} = 0$

Now corresponding to this we try to find out the solution as $y_2(t) = t^{\gamma_2}$, $y_2(t) = t$ to the power γ_2 summation $a_n t^n$ to the power n , n is from 0 to infinity. So γ_2 is $-1/2$ and a_n we have already calculated a_{2n} as -1 to the power n factorial $2n$, a_{2n+1} is simply 0 . So we can write it $y_2(t)$ as 1 upon root t because t to the power $-1/2$ is 1 upon root t and a_0 is 1 , so $1 - a_2 t^2$, t^4 square upon factorial 4 , a_4 is what? t to the power 4 upon factorial 4 .

A_4 is basically 1 upon factorial 4 and A_6 is going to be -1 upon factorial 6 t to the power 6 and so on. So if you look at this is 1 upon root t and in the bracket it is this term. So this is what? this is the formula of \cos of t . So $y_2(t)$ is written as 1 upon root t \cos of t and this is our

second solution or Bessel's equation of order 1/2 and we can write down the general solution and we can write down general solution $y(t)$ as $c_1 J_{1/2}(t) + c_2 Y_{1/2}(t)$. So this is our general solution of Bessel's equation of order 2.

(Refer Slide Time: 08:29)

Example

Consider the differential equation

$$x'' + \frac{p}{t^b} x' + \frac{q}{t^c} x = 0$$

where p and q are nonzero real numbers and b and c are positive integers and $x = 0$ is an irregular singular point if $b > 1$ or $c > 2$. Since $t = 0$ is a singular point as $P(t) = \frac{p}{t^b}$ and $Q(t) = \frac{q}{t^c}$ are not continuous at $t = 0$. Also, in case of $b = 1, c = 2$ the singular point $t = 0$ is a regular singular point as both $tP(t) = p$ and $t^2Q(t) = q$ are analytic function near $t = 0$. In particular, for $b = 2$ and $c = 3$, we have

$\pi(t)$
 $t=0$
 $t \frac{p}{t^b} = \frac{p}{t^{b-1}}$
 $\frac{p}{t^{b-1}}$
 $b > 1$
 $t^2 \frac{q}{t^c} = \frac{q}{t^{c-2}}$
 $\frac{q}{t^{c-2}}$
 $c > 2$

$$x(t) = \sum_{n=0}^{\infty} a_n t^{n+r}, \checkmark$$

$$x'(t) = \sum_{n=0}^{\infty} (n+r) a_n t^{n+r-1} \text{ and } x''(t) = \sum_{n=0}^{\infty} (n+r)(n+r-1) a_n t^{n+r-2}.$$

IIT ROORKEE
NPTEL ONLINE CERTIFICATION COURSE
24

Now so far we have discussed the case of regular singular point and we have seen that in case of regular singular point our possible solution is given in terms of summation $a_n t^{n+r}$ and by taking this as a solution we are plugging the value of y, y', y'' in the equation and with the help of the equation we try to find out an indicial equation from which we can find out the roots of the indicial equation.

And we try to find out the coefficient with the help of recurrence relation that we have already done. Now question comes that what happen if we have a singular point, but it is not a regular singular point. Then our question is can we apply the same method for which we have applied for regular singular point. So we are going to discuss 2 example which shows that to a certain extent we can do so, but not always.

So it means that that is why our method which we have already discussed is valid are working very good in the sense of regular singular point, but in case of irregular singular point we may not guarantee that our solution work or not. So let us consider the differential equation $x'' + \frac{p}{t^b} x' + \frac{q}{t^c} x = 0$. Here our unknown variable is x and independent variable is t .

So here we are writing our equation like this, xt . So here p and q are nonzero real numbers and b and c are positive integers and $x = 0$ is an irregular singular point. If $b > 1$ or $c > 2$. So first of all we can already check that $t = 0$ is a singular point because the coefficient of x dash and coefficient of x are not continuous at $t = 0$ and then we want to check where it is a regular singular point or not.

But if you take $b > 1$ or say $c > 2$ then we can check that the coefficient means t^p/t to the power b and t^q upon t to the power c may not be analytic function if b is greater than 1 or c is greater than 2. So either in each of these 2 cases we simply say that $t = 0$ is not an irregular singular point.

So here let us say that that is already written here that $t = 0$ is a singular point because t^p upon t to the power p and t^q upon t to the power c are not continuous $t = 0$ and also in the case of $b = 1$ and $c = 2$ that is the case which we have already discussed and we say that in case when $b = 1$ and $c = 2$ the singular point $t = 0$ is the regular singular point as both t^p and t^q are analytic function.

But in particularly if we take any value for b which is greater than 1 let us say $b = 2$ and let us say $c = 3$ value and we try to show that in this case we will get 1 Frobenius series solution so for that let us assume that solution is given as $x = \sum_{n=0}^{\infty} a_n t^{n+r}$. So here I am assuming that let us see whether this solution will work for this equation or not. We already know that for $b = 2$ and $c = 3$ your $t = 0$ is not a regular singular point. So let us see whether it will work or not.

For x dash t you calculate and x double dash t you calculate and that is summation $n = 0$ to infinity $a_n t^{n+r-1}$ and x double dash t is $n = 0$ to infinity $a_n t^{n+r-2}$. Now plug it back.

(Refer Slide Time: 12:44)

Example

So we have,

$$\begin{aligned}
 L[x] &= \sum_{n=0}^{\infty} (n+r)(n+r-1)a_n t^{n+r-2} + \sum_{n=0}^{\infty} p(n+r)a_n t^{n+r-3} \\
 &\quad + \sum_{n=0}^{\infty} qa_n t^{n+r-3} \\
 &= \sum_{n=1}^{\infty} \left[(n+r-1)(n+r-2)a_{n-1} + (p(n+r) + q)a_n \right] t^{n+r-3} \\
 &\quad + (pr+q)a_0 t^{r-3}
 \end{aligned}$$

Equating the sums of like power of t equal to zero, we get

$$\begin{aligned}
 &\text{(i) } (pr+q)a_0 = 0 \\
 &\text{(ii) } (n+r-1)(n+r-2)a_{n-1} + (p(n+r) + q)a_n = 0, \quad n \geq 1.
 \end{aligned}$$

So when you plug it back, you have $n = 0$ to infinity $n + r * n + r - 1$ and t to the power $n + r - 2$ + $n = 0$ to infinity $b * n + r$ and here it is what, here we are assuming that $b = 2$ here then it will give you an t to the power $n + r - 3$ and last term it is $n = 0$ to infinity q an t to the power $n + r - 3$, so here I am assuming that t or $c = 3$. So using this we have this term. Now just collect all the term and we write this as.

Look at the term of t to the power $r - 3$ here then here we have this term and this term will give you the coefficient of t to the power $r - 3$ and that is corresponding to $n = 0$ so that is what $pr + q a_0 * t$ to the power $r - 3$ is given when $n = 0$, but when you put $n = 1$ then this will give you the term t to the power $n + r - t$ to the power $r - 2$ so it means that then this term will also come into picture.

So it means that when you start from $n = 1$ to infinity, then this will give you what, this will give you $n + r - 1 * n + r - 2 a_{n-1}$, let us say, take the coefficient of t to the power $n + r - 0$. So here t to the power $n + r - 3$ will come when you take $n = c - 1$. So here we write $n + r - 1 * n + r - 2 a_{n-1} + Pn + r q a_n$. So basically what we are doing, we are just first calculating the coefficient of t to the power $r - 3$ that we can take it from this term as well as this term.

Now we want to write a general term. Let us say that general term is t to the power $n + r - 3$, so these 2 term is already given in terms of t to the power $n + r - 3$ so $p n + r + q * a_n$ that is already coefficient of t to the power $n + r - 3$ and if you look at from this term if you want to calculate the coefficient of t to the power $n + r - 3$ then you simply replace $n/n - 1$.

When you replace $n/n-1$ in this then you will get here $n = 12$ infinity $n + r-1 * n + r-2 a_{n-1}$. So from this you are getting this term. So it means that now we have, we simplify like this. Now equating the sums of like power of $t = 0$ so first let us say t to the power $r-3$ and we have $pr + q * a_0 = 0$ and then you write t to the power $n + r -3$ and that is valid when n is ≥ 1 .

So here when you put then we have $n + r-1 n + r-2, a_{n-1} + p n + r + q a_n = 0$ here. So from this in this first equation you can get your indicial equation as $pr + q = 0$.

(Refer Slide Time: 16:11)

Example

Equation (ii) forces $pr + q$ to be zero, and the recurrence relation (ii) says that

$$\checkmark a_1 = -\frac{(r-1)r}{p} a_0 \checkmark$$

$$\checkmark a_2 = -\frac{r(r+1)}{p} a_1$$

$$= \frac{(r-1)r^2(r+1)}{2p^2} a_0$$

$$\checkmark a_3 = -\frac{(r+1)(r+2)}{3p} a_2$$

$$= -\frac{(r-1)r^2(r+1)^2(r+2)}{3!p^3} a_0$$

$$r = -\frac{q}{p}$$

$$a_0 [r(r-1)] + [(1+r)p + q] a_1 = 0$$

$$a_1 = -\frac{r(r-1)}{(1+r)p + q} a_0$$

$$r = -\frac{q}{p} \Rightarrow 1+r = \frac{p-q}{p}$$

$$a_1 = -\frac{r(r-1) a_0}{p - q + q}$$

90

And we can simply say that here since it is a linear equation we will have only one solution that is $r = -q/p$ as your one root of indicial equation. So here please look at here since it is a irregular singular point then only we can say that here we are getting only one root of indicial equation. In fact, here indicial equation is not a quadratic equation, it is a simple linear equation.

So here one root we have obtained as $r = -q/p$. From this we try to calculate all other coefficients. So a_1 is basically what? so here to calculate a_1 let us look at here. So here when you put $n = 1$ then you will get a_1 in terms of a_0 . So use the second and put $n = 1$. So when you put $n = 1$ it is what? $p_1 + r + q a_1$. So that is what let me write it here.

So here we put $n = 1$ here then what you will get it is $r r-1 a_0 + p$ and $1 + r + q a_1 = 0$. So you can calculate your a_1 like this. So a_1 is coming out to be this value. So a_1 is going to be what? here this is $a_0 * r * r - 1 +$ here we have $1 + r P + q a_0 = 0$. So here you can get this is a_1 sorry, so $a_1 = -r * r - 1 a_0 / \text{this quantity } 1 + r p + q$ that we have already seen that it is this here.

Now let us use that value of r as $-q/p$, so using $r = -q/p$, then $1 + r$ is going to be $p-q$ upon p . So using this we can write this as a_1 as $-r * r-1 a_0$ /so it is $p-q + q$. So we can cancel out, so we can write a_1 as $-r-1r/p * a_0$. So a_1 is calculated and similarly you can calculate your a_2 and so on. So we can calculate all the coefficient using your recurrence relation 2 here.

(Refer Slide Time: 19:11)

Example

and in this way, we get

$$\checkmark a_n = \frac{(-1)^n (r-1)r^2(r+1)^2 \dots (r+n-2)^2(r+n-1)}{p^n n!} a_0, n \geq 2. \quad (15)$$

Hence, general solution is

$$\checkmark y(t) = \sum_{n=0}^{\infty} a_n t^{n+r} = \sum_{n=0}^{\infty} a_n t^{n-\frac{p}{q}}$$

where a_n is given by (15).

$t=0$

$r = -\frac{p}{q}$

27

And we can say that our solution is calculated like this, $a_n = -1$ to the power $n-1$ r square $r+1$ and so on and p to the power n factorial n that is $n \geq 1$ here. So we can write down our solution as $y(t)$ as summation $n = 0$ to infinity $a_n t$ to the power $n+r$ and r is given as $-p/q$. So even if here $t = 0$ is your singular point not only singular point it is irregular singular point but still we are able to find out series solution in fact Frobenius series solution in case of irregular singular point.

So here since $t = 0$ is a weak irregular singular point then we can find out one solution of this form. We are not able to find out the second solution of the form of Frobenius series solution. So how to find out the second series solution for that you can use your variation of parameter method or any given method. So here in this case we have seen that one solution we can obtain.

Now let us, now I am leaving it to you that here I am assuming that your $b = 2$ and $c = 3$. Now I simply say that if you take $b = 3$ and $c = 4$ in that case you will not have any solution of the form of Frobenius series that I am leaving it to you, that check that when case $b = 3$

and $c = 4$ we do not have any solution of the form of Frobenius series. Of course it will have a solution but not of the form of Frobenius series solution.

So here we simply say that here $t = 0$ is a weak irregular singular point of this differential equation. Now let us consider one more example and example is this.

(Refer Slide Time: 21:19)

Example

For $b = 1$ and $c = 2$, differential equation (14) becomes

$$x'' + \frac{p}{t}x' + \frac{q}{t^2}x = 0$$

$$x(t) = \sum_{n=0}^{\infty} a_n t^{n+r},$$

therefore

$$x'(t) = \sum_{n=0}^{\infty} (n+r)a_n t^{n+r-1} \text{ and } x''(t) = \sum_{n=0}^{\infty} (n+r)(n+r-1)a_n t^{n+r-2}.$$

28

We already know that for $b = 1$ and $c = 2$ your differential equation is reduced to this and that is your $x'' + p/t x' + q/t^2 x = 0$. If you look at this is nothing but your Cauchy-Euler equation right. This is a simple Cauchy-Euler equation and we can simply say that here also if you want to apply the solution $x = t^n$ from $n = 0$ to infinity and t to the power $n + r$.

(Refer Slide Time: 21:49)

Example

So we have,

$$L[x] = \sum_{n=0}^{\infty} (n+r)(n+r-1)a_n t^{n+r-2} + \sum_{n=0}^{\infty} p(n+r)a_n t^{n+r-2} + \sum_{n=0}^{\infty} qa_n t^{n+r-2}$$

$$= \sum_{n=0}^{\infty} \left[(n+r)(n+r-1) + p(n+r) + q \right] a_n t^{n+r-2}$$

Equating the sums of like power of t equal to zero, we get

$$\underline{(n+r)(n+r-1) + p(n+r) + q = 0} \cdot \underline{F(n+r)a_n t^{n+r} = 0}$$

29

And similarly calculating x^{-t} , x^{-2t} we can simply say that $lx =$ what $n = 0$ to infinity $n + r * n + r - 1$ an t to the power $n + r - 2 + n = 0$ to infinity $p n + r$ an t to the power $n + r - 2 + q = 0$ to infinity q an t power $n + r - 2$ and if you calculate coefficient will be what, $n = 0$ to infinity $n + r n + r - 1 + p n + r + q * an t$ to the power $n + r - 2$ so here we say that here when you start from $n = 0$ your all terms will come into picture.

So equating the sums of like power of $t = 0$ will get this term, so this is your general term, so here we write f of $n + r$ an t to the power $n + r = 0$, so here F_{n+r} is given by $n + r * n + r - 1 + p n + r + q = 0$ here.

(Refer Slide Time: 22:46)

Example

i.e. ' r ' satisfies a quadratic equation and there might exist two distinct Frobenius series solutions.

And we can simply say that here this indicial equation when you put $n = 0$ your indicial equation is what, this indicial equation is a quadratic indicial equation and this will give you 2 roots of indicial equation and we with the help of 2 roots we can find out 2 solutions. One solution is given surely in terms of Frobenius series solution and the other you can get depending on the cases.

But here if you look at this is a simple Cauchy-Euler equation and we can simply say that if you put $n = 0$ here then it is what $r * r - 1 + p r + q = 0$ and it is the indicial equation which you have obtained for Cauchy-Euler equation. So we simply say that Cauchy-Euler equation is the simplest case of irregular singular point and we can use the method to find out the solution for the Cauchy-Euler equation.

And we have already seen that t to the power r_1 and t to the power r_2 by suitably defining r_1 and r_2 we can get other solution like this.

(Refer Slide Time: 24:11)

Example

$t p(t) = \frac{(3t-1)}{t} = 3 - \frac{1}{t}$

Consider the differential equation

$$t^2 y'' + (3t - 1)y' + y = 0 \quad (16)$$

$t = 0$
 $P(t) = \frac{(3t-1)}{t^2}$
 $Q(t) = \frac{1}{t^2}$

therefore

$$x'(t) = \sum_{n=0}^{\infty} (n+r) a_n t^{n+r-1} \text{ and } x''(t) = \sum_{n=0}^{\infty} (n+r)(n+r-1) a_n t^{n+r-2}.$$

IIT ROORKEE
NPTL ONLINE CERTIFICATION COURSE
31

Now look at one more example here also if you look at example is what $t^2 y'' + 3t - 1 y' + y = 0$. If you look at here also $t = 0$ is a singular point, so because here $p(t)$ is what? $p(t)$ is your $3t - 1/t$ square and $q(t)$ is what? $q(t)$ is 1 upon t square. So we simply say that $p(t)$ and $q(t)$ are not continuous. So $t = 0$ is a singular point. Now just look at whether it is a regular singular point or not.

So look at $t p(t)$, so $t p(t)$ is coming out to be $3t - 1/t$ or you can say $3 - 1/t$ and you say that this is not analytic function. So it means that here this $t p(t)$ feels to be analytical so it means that $t = 0$ is the case of irregular singular point. Right so if it is a irregular singular point and still if you want to find out that whether the method which is given for regular singular point will work for this or not.

Let us assume our solution $y(t)$ as summation $n = 0$ to infinity $a_n t^{n+r}$ and just calculate y' and y'' and so on and put it back to equation what you will see.

(Refer Slide Time: 25:19)

Example

So we have,

$$L[x] = \sum_{n=0}^{\infty} (n+r)(n+r-1)a_n t^{n+r} + \sum_{n=0}^{\infty} (3t-1)(n+r)a_n t^{n+r-1}$$

$$+ \sum_{n=0}^{\infty} a_n t^{n+r}$$

$$= \sum_{n=1}^{\infty} [(n+r)^2 a_{n-1} - (n+r)a_n] t^{n+r-1} - r a_0 t^{r-1}$$

Equating the sums of like power of t equal to zero, we get

(i) $r a_0 = 0$ $r > 0$

(ii) $(n+r)^2 a_{n-1} - (n+r)a_n = 0, \quad n \geq 1.$

It is $n = 0$ to infinity $n + r - 1$ and t to the power $n + r$ + summation $n = 0$ to infinity $3t - 1$ $n + r$ $a_n t$ to the power $n + r - 1$ + summation $n = 0$ to infinity $a_n t$ to the power $n + r$. Now here if you simplify you will get what? so here let us calculate the coefficient of t to the power $n + r$. So here this term and this term will contribute in t to the power $n + r$ and this will give a term of like if you multiply $3t$ into this then it will also contribute in t to the power $n + r$ and if you look at this term will simply say the term of t to the power $n + r - 1$.

So your term when you put $n = 0$ then this will give you, let me write it, $n = 0$ here then corresponding to this you will get $-r a_0 t$ to the power $r - 1$, which I am writing here. So this is the term which we obtain by putting $n = 0$ in the second term and then when you put $n = 1$ and onward then all other term will also contribute and we say that in general if we look at the coefficient of t to the power $n + r - 1$ then from first term we get t to the power $n + r - 1$ if we replace n by $n - 1$.

Then it is what n , let me write it here, so we just want to calculate t to the power $n + r - 1$, so first term will give you what? $n + r - 1 * n + r - 2$, I am replacing n by $n - 1 * a_{n-1}$ fine, from this I can write 3 and it is what $n + r - 1$ and again a_1 , I am writing because of this, because this will not give term like this. So here we will get like this. This is $a_1 +$, if we multiply - here then what do you will get.

It is a_{n-1} from last you will get a_{n-1} and if you just calculate here it is a_{n-1} and if you calculate this is what you write this as what? $n + r - 1$ you take it out then it is what $n + r - 2 + 3$. So we will get $n + r + 1$ then there is one more term left out because of this that is here I have

to write one more term that is here $-n + r a_n$, so that I am writing here, so we will get $n + r - 1 + n + r + 1 a_{n-1} - n + r a_n$.

And these are the coefficients of t to the power $n + r - 1$, which I am writing here, so if you simplify it is what? so here we are calculating the coefficient of t to the power $n + r - 1$ so one term we are getting from this by replacing n by $n - 1$ that is $n + r - 1 * n + r - 2 * a_{n-1}$ here we are getting term from this then here $3n + r - 1 a_{n-1}$ so writing $3n + r - 1 a_{n-1}$ and 1 we are getting from here when we replace n by $n - 1$.

Here we are writing a_{n-1} , and the term corresponding to t to the power $n + r - 1$ we are getting from this then we are getting $-n + r a_n$ and when you simplify $n + r - 1 * n + r - 2 + 3n + r - 1 + 1$ and we write it like this. So $n + r - 1 * n + r + 1 + 1 * a_{n-1} - n + r a_n * t$ to the power $n + r - 1$ when you simplify this you will get what? $n + r$ whole square $-1 + 1$. So it is $n + r$ whole square a_{n-1} , $-n + r a_n$ t to the power $n + r - 1$ when we start from $n = 1$ to infinity.

And then because you are replacing n by $n - 1$, so $n - 1 = 0$ means n starting from 1 onward. So it means that here we have the lowest degree term is t to the power $r - 1$ so equating the lowest degree term t to the power $r - 1$ is 0. So we will get $r a_0 = 0$ and then you write n to the power $r - 1$ so equating the coefficient of t to the power $n + r - 1$ we are getting this recurrence solution that is $n + r$ whole square $a_{n-1} - n + r a_n = 0$.

That is for $n \geq 0$. So if you look at the first equation a_0 cannot be 0 so r has to be 0. So this will again give you a linear indicial equation and here you will get only one root of indicial equation that is $r = 0$ so here we have $r = 0$.

(Refer Slide Time: 30:54)

Example

For non trivial solution $a_0 \neq 0 \Rightarrow r = 0$. and the recurrence relation (ii) says that

$$\begin{aligned}
 \checkmark a_1 &= a_0 & a_n &= (n+r)a_{n-1} \\
 a_2 &= 2a_1 = 2a_0 & a_n &= n a_{n-1} \quad n \geq 1 \\
 a_3 &= 3a_2 = 3!a_0 & a_1 &= a_0 \\
 & & a_2 &= 2 \cdot a_1 \\
 & & a_3 &= 3 \cdot a_2
 \end{aligned}
 \tag{17}$$

and in this way, we get

$$a_n = n! a_0, \quad n \geq 2.$$

Hence, general solution is

$$y(t) = \sum_{n=0}^{\infty} a_n t^{n+r} = \sum_{n=0}^{\infty} n! t^n$$

which converges only at $x = 0$, so it is not a valid solution.

Now we with the help of this root of this indicial equation we try to find out other a_n . So you can simply say that $a_n = ?$ $a_n = n + r a_{n-1}$ so here you have a_n as $n + r$ you can cancel out because n is positive r is 0, so you can cancel out $n + r$, so a_n is given as $n + r a_{n-1}$ and $r = 0$, so $a_n = n a_{n-1}$. So here if you start since n is ≥ 1 , so let us start with $n = 1$ itself so $a_1 = a_0$ that we have listed here and using this a_2 is what.

$a_2 = n=2$ so $2 * a_1$ so it is $2 * a_1$ that is $2 * a_0$. Similarly, a_3 is what $3 * a_2$, a_2 is $2 * a_1$. So we can write it that a_3 is given as factorial 3 a_0 and we can use mathematical induction to show that a_n is given as factorial $n a_0$ and n is ≥ 2 . So hence general solution we can write it as $y(t) = \sum_{n=0}^{\infty} a_n t^{n+r}$ that is $\sum_{n=0}^{\infty} n! t^n$ to the power n .

So here theoretically we can say that it looks that we got a solution and solution is given by $\sum_{n=0}^{\infty} n! t^n$, but if you have already seen the theory of power series that this power series has 0 radius of convergence that you can calculate using your tools that you can find out that radius of convergence is coming out to be 0. So it means that this power series is actually not a power series because it will never converge.

It will converge only the point at $t = 0$. So it means that this is not a valid solution $r t = 0$, so it means that here we have seen that though it looks that our solution workout very fine and we are getting a solution but actually this series solution is having radius of convergence as 0. It means that this is not a series solution of this equation and here we can say that here $t = 0$ is a irregular singular point.

But we are not getting a single solution of the form of Frobenius series but in previous example though $t = 0$ is your irregular singular point, but still we are able to find out one series solution the form of Frobenius form. So here we say that $t = 0$ is a strong irregular singular point. So that we want to convey that when point is not irregular singular point that we may not guarantee that a series solution exist or not.

Because in first case we have seen that series solution exist and it is given by form which we have already discussed but here in the second case your $t = 0$ is a irregular singular point, but here your solution you can say that it looks like that it is given as a Frobenius series form but actually it has no radius of convergence so we simply say that it has, it is not Frobenius series solution.

So it means that in case of irregular singular point our method of assuming the solution as Frobenius series form may not work at all. So here we want to give a message that when we have a regular singular point then we can find out a best solution using Frobenius series solution but if it is not a regular singular point then we have several other methods to find out solution but this Frobenius series solution may not work.

So with this I conclude the study of Frobenius series solution method of linear second order differential equation. Thank you for listening us. Thank you.
