Turbulent Flows - I
Lecture - 03
External Turbulent Flows

Hello, everyone. In last class we derived the Reynolds average Navier Stoke equations and we have seen that there are additional 9 terms appearing due to the velocity fluctuations. Out of these 9 additional components, we have 6 unknowns. Today, we will consider external flows, flow over flat plate and we will simplify these equations and we will try to model these unknowns.

(Refer Slide Time: 01:06)

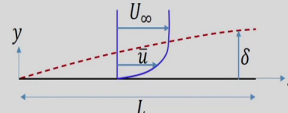

Turbulent Boundary Layer Equations

Consider two-dimensional steady state, incompressible flow with constant properties.

Continuity equation:

$$\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} = 0 \quad \checkmark$$

Assume $\delta \ll L$

x – component momentum equation:

$$\rho \left(\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} \right) = -\frac{\partial \bar{p}}{\partial x} + \mu \left(\frac{\partial^2 \bar{u}}{\partial x^2} + \frac{\partial^2 \bar{u}}{\partial y^2} \right) - \rho \frac{\partial (\overline{u'u'})}{\partial x} - \rho \frac{\partial (\overline{u'v'})}{\partial y} \quad \checkmark$$

y – component momentum equation:

$$\rho \left(\bar{u} \frac{\partial \bar{v}}{\partial x} + \bar{v} \frac{\partial \bar{v}}{\partial y} \right) = -\frac{\partial \bar{p}}{\partial y} + \mu \left(\frac{\partial^2 \bar{v}}{\partial x^2} + \frac{\partial^2 \bar{v}}{\partial y^2} \right) - \rho \frac{\partial (\overline{u'v'})}{\partial x} - \rho \frac{\partial (\overline{v'v'})}{\partial y} \quad \checkmark$$

So, consider two-dimensional steady state incompressible flow with constant properties. So, this is a flat plate, flow over flat plate is taking place, this is the boundary layer thickness δ , L is the length of the flat plate, \bar{u} is the time averaged velocity and it is varying in the boundary layer and outside we have free stream velocity U_∞ . When you are considering turbulent boundary layer equations so; obviously, δ will be much much smaller than L .

So, this is the continuity equations we have derived in last class and this is the x component of momentum equations as you are considering two-dimensional situation. So, we have two additional terms in the x component of momentum equations. Similarly, in y component of momentum equations, we have two additional terms. If we consider turbulent boundary layer flow, so, let us check which are the terms, actually we can drop from these equations.

As we derived the boundary layer equation for laminar flow, we will follow the similar scale analysis and we will try to see that which is term is very very small compared to the other. So, here the scale will take x as L and y as boundary layer thickness δ . And; obviously, as you are considering boundary layer flow δ is much much smaller than L .

(Refer Slide Time: 02:56)

Turbulent Boundary Layer Equations

Assume $\delta \ll L$

Scales $\bar{u} \sim U_\infty$ $x \sim L$ $y \sim \delta$

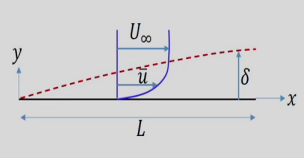

$$\frac{\partial^2 \bar{u}}{\partial x^2} \ll \frac{\partial^2 \bar{u}}{\partial y^2}$$

For isotropic turbulence, $u' \sim v'$

$$\frac{\partial(\overline{u'u'})}{\partial x} \sim \frac{u'u'}{L} \quad \frac{\partial(\overline{u'u'})}{\partial y} \sim \frac{u'u'}{\delta}$$

$$\delta \ll L, \quad \frac{\partial(\overline{u'u'})}{\partial x} \ll \frac{\partial(\overline{u'u'})}{\partial y}$$

x - component momentum equation:

$$\rho \left(\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} \right) = -\frac{\partial \bar{p}}{\partial x} + \mu \left(\frac{\partial^2 \bar{u}}{\partial x^2} + \frac{\partial^2 \bar{u}}{\partial y^2} \right) - \rho \frac{\partial(\overline{u'u'})}{\partial x} - \rho \frac{\partial(\overline{u'v'})}{\partial y}$$

So, using this scale; obviously, you can see that $\frac{\partial^2 \bar{u}}{\partial x^2}$ will be much much smaller than $\frac{\partial^2 \bar{u}}{\partial y^2}$.

Now, if we consider isotropic turbulence then; obviously, this u' will be order of v' ok. So, if it is so, then you can write $u' u'$ will be order of $u' v'$. Now, if you take the time average, then $\overline{u' u'}$ will be order of $\overline{u' v'}$. So, now, if you take the gradient then, we can write that $\frac{\partial \overline{u' u'}}{\partial x}$ will be order of so, you can write $\overline{u' u'}$ and x is order of L .

And, similarly you can see that for the other term in the x component momentum equation, we have $\frac{\partial \overline{u' v'}}{\partial y}$ ok. So, this also we can write here it will be bar. So, will be order of $\overline{u' v'}$ and y scale is δ . Now, you compare these two ok. So,

you can see that already we have shown that $u' \bar{u}'$ will be order of $u' \bar{v}'$; that means, in the numerator these are of same order right.

So, you can see if δ is much much smaller than L ok; obviously, $\frac{\partial u'}{\partial x}$ will be much much smaller than $\frac{\partial \bar{v}'}{\partial y}$ ok. So, obviously, you can see that this term is very very small compared to this term. So, now, if you see the x component momentum equation, so, from the viscous term ok you can see here. So, $\frac{\partial^2 \bar{u}}{\partial x^2}$ is much much smaller than $\frac{\partial^2 \bar{u}}{\partial y^2}$.

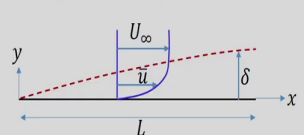

So, we can drop this term ok. And if you compare these two terms then; obviously, this is very small compared to the other. So, we can drop this term ok. So, you can see that we have simplified this turbulent boundary layer equation ok, for the x component of momentum equation as this. Now, let us consider the y component of momentum equation, we know that \bar{v} is very very small compared to the \bar{u} so, that we can show from the continuity equation.

(Refer Slide Time: 06:21)

Turbulent Boundary Layer Equations

Assume $\delta \ll L$

Scales
 $\bar{u} \sim U_\infty \quad x \sim L \quad y \sim \delta$

y - momentum equation reduces to

$$0 = -\frac{\partial \bar{p}}{\partial y} - \rho \frac{\partial(\overline{v'v'})}{\partial y} \quad \checkmark$$

$$\bar{p} \approx p_\infty - \rho \overline{v'v'}$$

$$\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} = 0$$

$$\frac{\partial \bar{v}}{\partial y} \sim \frac{\partial \bar{u}}{\partial x}$$

$$\bar{v} \sim \frac{U_\infty \delta}{L}$$

$$\delta \ll L$$

It is seen that v' fluctuations are no more than 4% of U_∞ . Thus pressure differs from \bar{p} by no more than 0.4% of the p_∞ . This is negligible variation. So $\frac{\partial \bar{p}}{\partial y} = 0$, $\frac{\partial \bar{p}}{\partial x} \approx \frac{dp_\infty}{dx} \approx \frac{dp_\infty}{dx}$

So, what is our continuity equation? $\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} = 0$. So, from here you can see $\frac{\partial \bar{v}}{\partial y}$ will be order of $\frac{\partial \bar{u}}{\partial x}$. So, \bar{v} will be order of δ , this will be U_∞ ok, x is L and y is δ ok. And; obviously, δ is much much smaller than L .

So, δ/L is much much smaller than 1. So, \bar{v} will be very very small compared to U_∞ ok. So, you can see that from here the terms in the y component momentum equation, the viscous term and the inertia terms you can neglect and you will get this y component of momentum equation as this ok. And from here you can see that \bar{p} you can write as $p_\infty - \rho \overline{v'v'}$ ok.

So, it is seen that v' fluctuations are no more than 4 percent of U_∞ ok. Thus pressure differs from \bar{p} by no more than 0.4 percent of the p_∞ . So, this is negligible

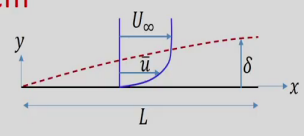

variation. So, we can write $\frac{d\bar{p}}{dy}$ is equal to 0. So, if $\frac{d\bar{p}}{dy}$ is equal to 0. So, $\frac{d\bar{p}}{dx}$ we can write $\frac{d\bar{p}}{dx}$, which we can write also $\frac{d p_\infty}{dx}$ where p_∞ is the free stream pressure ok outside the boundary layer.

So, using scale analysis, we have dropped some terms in the x momentum equations and from y component of momentum equations we have shown that normal pressure gradient is 0.

(Refer Slide Time: 08:30)

Closure Problem

Consider flow over flat plate

$$\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} = 0 \quad \checkmark$$

0 for flow over flat plate

$$\rho \left(\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} \right) = - \frac{d\bar{p}}{dx} + \frac{\partial}{\partial y} \left(\mu \frac{\partial \bar{u}}{\partial y} - \rho \overline{u'v'} \right) \quad \checkmark$$

Boundary Conditions:
 @ $y = 0, \bar{u} = 0, \bar{v} = 0$
 @ $y \rightarrow \infty, \bar{u} = U_\infty \checkmark$
 @ $x \rightarrow 0, \bar{u} = U_\infty$

There are two equations and three unknowns, $\bar{u}, \bar{v}, \overline{u'v'}$.
 This is the **closure problem** of turbulence.

$-\rho \overline{u'v'}$ is called the turbulent shear stress or the Reynolds stress. \checkmark

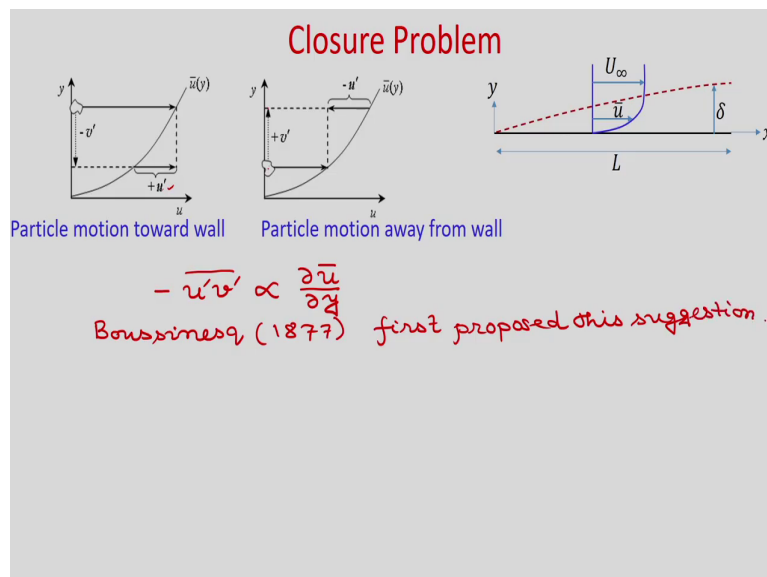

Now, we can write the simplified equations as this is the continuity equation and if we consider flow over flat plate. So, $\frac{d\bar{p}}{dx}$ will be 0. So, and we will have this term ok.

So, what are the boundary conditions? You can see at y is equal to 0; obviously, \bar{u} is equal to 0 \bar{v} is equal to 0 and y tends to infinity, \bar{u} is equal to infinity and x tends to 0 near to the leading edge \bar{u} is equal to u_∞ ok.

So, now, you can see, we have two equations right, continuity equation and this simplified x component momentum equation ok. And how many unknowns are there? So, you can see we have \bar{u} \bar{v} and this $\overline{u'v'}$.

So, there are two equations and three unknowns ok. So, this is the closure problem of turbulence, because these we have lesser number of equation than unknowns. So, this term minus $\rho \overline{u'v'}$ is called the turbulent shear stress or Reynolds stress.

(Refer Slide Time: 10:01)

Now, question is how to model this term? So, this unknown term, let us see that whether we can model using the velocity gradient ok. Considered a fluid particle fluctuation imposed on some average velocity profile ok. So, you can see that at this location; obviously, it is having some velocity, if this fluid particle comes to this position ok in the negative y direction so;

obviously, it will have some higher velocity. So, what it will do. So, this fluid particle will try to accelerate or move this particle at a velocity $u' + u'$ ok.

So, you can see that relative to the local velocity the fluid particle has a velocity that is higher by a value of plus u' . So, the velocity fluctuation in y direction minus v' , results in a velocity fluctuation in x direction plus u' . So, it appears that magnitude of u' depends on the slope of the mean velocity profile. So, you can see that we can write these component $u' v'$ in terms of mean velocity gradient.

Similar way you consider this fluid particle at this position which is having lesser velocity than at this point. So, due to this fluctuation plus v' these particle moves here then; obviously, it will try to retire the flow with a velocity minus u' . So, you can see that when minus v' we have this velocity fluctuation, we have this plus u' . So, now, we can write that like viscous shear stress time average fluctuations is also proportional to the velocity gradient.

So, that we can write that minus $u' v' \bar{}$ is proportional to the average velocity gradient.

(Refer Slide Time: 12:55)

Eddy Viscosity

Based on Boussinesq's hypothesis, we can model Reynolds stress as follows,

$$-\rho \overline{u'v'} = \rho \nu_t \frac{\partial \bar{u}}{\partial y} \quad \rho \nu_t \text{ - momentum eddy diffusivity or eddy viscosity}$$

$$\rho \left(\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} \right) = \frac{\partial}{\partial y} \left[(\mu + \rho \nu_t) \frac{\partial \bar{u}}{\partial y} \right]$$

$$\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} = \frac{\partial}{\partial y} \left[(\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} \right]$$

Apparent shear stress $\frac{\tau_{app}}{\rho} = (\nu + \nu_t) \frac{\partial \bar{u}}{\partial y}$
molecular viscosity → property of the fluid

ν_t is **property of the flow** (not the fluid).

Velocity field

So, this was actually proposed by a Boussinesq in 1877 first proposed this suggestion. Now, based on this Boussinesq hypothesis, we can model Reynolds stress as follows. So, you can write minus rho u prime v prime bar ok. So, you can write so, this rho u prime v prime bar is proportional to del u bar by del y.

So, we can write with some constant nu t rho nu t del u bar by del y, where rho nu t is known as momentum eddy diffusivity or eddy viscosity ok. So, this rho nu t is momentum eddy diffusivity and this nu t; obviously, is unknown ok. So, if we model using this Boussinesqs hypothesis like this, then the in the right hand side we can write minus rho u prime v prime bar as rho nu t del u bar by del y and already we have molecular viscosity.

So, now, you have written this equation just dividing the ρ in the right hand side. So, we can write $\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y}$ is equal to $\frac{\partial}{\partial y} \tau$. So, τ by ρ is ν_t and this will be just $\nu_t \frac{\partial \bar{u}}{\partial y}$.

So, you can see that using Boussinesq's hypothesis these fluctuations we have written like this and here only unknown term is ν_t ok. So, here we can write this term as apparent shear stress. So, τ_{app} by ρ is equal to $\nu + \nu_t \frac{\partial \bar{u}}{\partial y}$. So, ν ; obviously, you can see that this is molecular viscosity and it is a property of the fluid. However, ν_t is not property of the fluid, ν_t depends on the velocity field and ν_t is property of the flow ok.

So, here this is your molecular viscosity ok so; obviously, this is property of fluid; however, this ν_t term is property of the flow. Now, you can see that how to model this ν_t right. Because it is unknown and in boundary layer equation we do not have any exact solutions, we can either use some numerical techniques or we can use some integral method with some approximation.

(Refer Slide Time: 15:49)

Prandtl's Mixing Length Theory

How to model ν_t ?

Boussinesq postulated that ν_t was constant. ✓
 Constant ν_t does not allow $\overline{u'v'}$ to approach zero at the wall.

Prandtl defined the mixing length l as the distance the particle travels as the result of a fluctuation.

The velocity fluctuation u' that results can be approximated from a Taylor series as

$$u_{final} \approx u_{initial} + dy \frac{\partial \bar{u}}{\partial y}$$

$$u' = u_{final} - u_{initial} \approx dy \frac{\partial \bar{u}}{\partial y}$$

$u' \sim l \frac{\partial \bar{u}}{\partial y}$ ✓ For isotropic turbulence, $v' \sim l \frac{\partial \bar{u}}{\partial y}$ ✓ $-\overline{u'v'} \sim u'v' \sim l^2 \left(\frac{\partial \bar{u}}{\partial y}\right)^2$

$\nu_t = \frac{-\overline{u'v'}}{\frac{\partial \bar{u}}{\partial y}} \sim l^2 \left| \frac{\partial \bar{u}}{\partial y} \right|$ The absolute value is imposed on the derivative to ensure that the eddy diffusivity remains positive.

Prandtl proposed the following model for the mixing length: $l = \kappa y$

Leading to Prandtl's mixing-length model: $\nu_t = \kappa^2 y^2 \left| \frac{\partial \bar{u}}{\partial y} \right|$ ✓

So, to model this ν_t Boussinesq postulated that ν_t was constant ok. So, constant ν_t does not allow $\overline{u'v'}$ to approach zero at the wall. So, Prandtl defined the mixing length l as the distance the particle travels as the result of fluctuation.

So, you can see that when this fluid particle comes to this position with a fluctuation of minus v' ok it results in a velocity of plus u' . So, you can see that this we can actually use this length as mixing length and Prandtl define this mixing length l as the distance the particle travels as result of fluctuation.

So, these velocity fluctuation u' that results can be approximated from a Taylor series ok. So, if it is u_{final} here this is $u_{initial}$. So, u_{final} we can use Taylor series expansion and can write $u_{initial} + dy \frac{\partial \bar{u}}{\partial y}$ ok. So, obviously, the difference in the velocity u

final minus u initial is u' that we can write as $dy \frac{d\bar{u}}{dy}$ and this dy , we can write as a mixing length l . So, you can write u' is order of $l \frac{d\bar{u}}{dy}$ ok.

And for isotropic turbulence, we know that u' is order of v' . So, v' will be ordered of $l \frac{d\bar{u}}{dy}$. And, here you can see that if you take the time average of this minus $u'v'$ bar. So, we will get this as $l^2 \frac{d\bar{u}}{dy}$. Because these two terms and we can see that; obviously, this minus $u'v'$ bar will be positive quantity because, you can see that when v' is negative u' is positive right.

So, when we consider minus $u'v'$ due to this negative sign; obviously, this will be a positive quantity. Similar way we have also discussed that when this fluid particle goes in the upward direction with a fluctuation v' , it results a velocity in minus u' . So, you can see that this product of $u'v'$ will be negative. So, this quantity itself will be a positive.

So, now as you have used this Prandtl's mixing length theory to express this minus $u'v'$ bar as $l^2 \frac{d\bar{u}}{dy}$, where l is the mixing length. And now, we can write ν_t that minus $u'v'$ bar divided by $\frac{d\bar{u}}{dy}$ right. So, this term we have now used this expression. So, we can see we can write it as $l^2 \frac{d\bar{u}}{dy}$ ok.

So, we are use this absolute value because ν_t is positive ok. So, the absolute value is imposed on the derivative to ensure that the eddy diffusivity remains positive ok. So, now, Prandtl propose the following model for the mixing length so, because l is also unknown right. So, Prandtl propose this mixing length l as equal to κy ok and leading to Prandtl's mixing length model. So, ν_t we can write l as κy . So, $\kappa^2 y^2$ absolute value of $\frac{d\bar{u}}{dy}$.

So, this is the expression of this eddy viscosity using Prandtl's mixing length theory. Where κ is unknown that is to be determined from the experimental results. We are considering flow over plate so, it is nearly parallel flow.

(Refer Slide Time: 20:20)

Universal Turbulent Velocity Profile

Assume that the flow is nearly parallel close to the wall, i.e. $\bar{v}=0$.

$$\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y} = 0 \quad \checkmark$$

$$\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} = \frac{\partial}{\partial y} \left[(\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} \right] \quad \checkmark$$

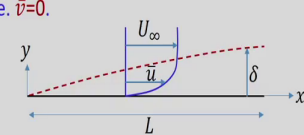

Near wall

$$\frac{\partial}{\partial y} \left[(\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} \right] \approx 0$$

$(\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} = \text{const.}$

Apparent shear stress

$$\frac{\tau_{app}}{\rho} = \frac{\tau_w}{\rho} = (\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} \approx \text{constant} \quad \checkmark$$

So, we can assume that \bar{v} as 0. So, you can see that we have this continuity equation and this is the turbulent boundary layer momentum equation ok.

Where ν_t is eddy viscosity and that using Prandtl's mixing length hypothesis, we have expressed as $\kappa^2 y^2 \frac{\partial \bar{u}}{\partial y}$. So, now, if you consider near wall region ok so; obviously, \bar{u} and \bar{v} will be 0. So, from here you can see that if \bar{v} is 0. So, this term will become 0 and \bar{u} will be very very small. So, this term will be 0. So, in near wall we can write this term is equal to 0.

So; obviously, you can see that if this term is 0, then $\nu + \nu_t$ if you integrate it ok. So, it will be constant ok. So, obviously, then we have already expressed this apparent viscosity by ρ ok.

So, that we can write as at the wall; obviously, we can write τ_w by ρ is equal to ν plus ν_t del \bar{u} by del y which is constant. Now, let us see that when we can drop one of these two terms because this is your molecular viscosity, ν which is very prominent near to the wall and ν_t you can see that it is due to the fluctuating components.

(Refer Slide Time: 22:04)

Universal Turbulent Velocity Profile

Dimensional analysis shows that the following coordinates will collapse the boundary layer velocity data into a single curve reasonably well.

$$u^+ = \frac{\bar{u}}{u_\tau}$$

$$y^+ = \frac{y u_\tau}{\nu}$$

$$u_\tau = \sqrt{\frac{\tau_w}{\rho}} \text{ - friction velocity}$$

$$y^+ \text{ - local Reynolds number}$$

$$(v + \nu_t) \frac{\partial \bar{u}}{\partial y} = \frac{\tau_w}{\rho}$$

$$(\nu + \nu_t) \frac{u_\tau}{y} \frac{\partial u^+}{\partial y^+} = \frac{\tau_w}{\rho}$$

$$\Rightarrow (1 + \frac{\nu_t}{\nu}) \frac{u_\tau^2}{y} \frac{\partial u^+}{\partial y^+} = \frac{\tau_w}{\rho}$$

$$\Rightarrow (1 + \frac{\nu_t}{\nu}) \frac{\partial u^+}{\partial y^+} = 1$$

$$\Rightarrow u^+ = \int_0^{y^+} \frac{dy^+}{(1 + \frac{\nu_t}{\nu})}$$

Divide the boundary layer into two near-wall regions:

- A region very close to the wall where viscous forces dominate
- A region where turbulent fluctuations dominate

So, away from the wall this ν_t will dominate the flow. Dimensional analysis shows that the following coordinates will collapse the boundary layer velocity data into a single curve reasonably well. So, we will use these non-dimensional parameters u^+ which is the ratio of mean velocity \bar{u} divided by u_τ , where u_τ is the friction velocity ok which is $\sqrt{\tau_w / \rho}$ ok. And y^+ it is the non-dimensional y coordinate which is equal to $y u_\tau$ by ν , where u_τ is the friction velocity and ν is the molecular viscosity ok.

So, from here you can see that this equation already we have written in terms of the wall shear stress τ_w . So, now, you can see that we can use these non-dimensional parameters, we can write this equation as. So, $1 + \frac{\nu_t}{\nu}$. So, this \bar{u} is $u + u'$. So, you can write $\frac{\nu_t}{\nu} \frac{d\bar{u}}{dy}$ ok. So, $\frac{d\bar{u}}{dy}$ if you write. So, it will be $\frac{\nu_t}{\nu} \frac{d\bar{u}}{dy}$. So, it will be $\frac{\nu_t}{\nu} \frac{d\bar{u}}{dy}$, but in the denominator we will have ν by ν_t and in the right hand side we have τ_w by ρ .

So, now if you divide ν here so, you will get $1 + \frac{\nu_t}{\nu}$ and you can see it will be $\frac{\nu_t}{\nu}$ square right, it will be $\frac{\nu_t}{\nu}$ square sorry, this will be $\frac{\nu_t}{\nu}$ plus. So, it will be $\frac{\nu_t}{\nu} \frac{d\bar{u}}{dy}$ plus is equal to $\frac{\tau_w}{\rho}$. Now, here you can see that $\frac{\nu_t}{\nu}$ square is $\frac{\tau_w}{\rho}$. So, these will get cancel ok. So, we can write $1 + \frac{\nu_t}{\nu} \frac{d\bar{u}}{dy}$ plus is equal to $\frac{\tau_w}{\rho}$ ok.

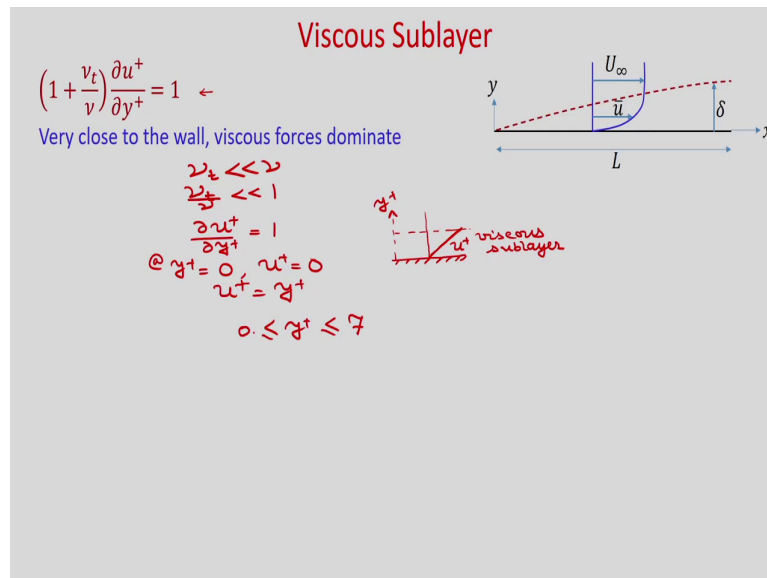

So, now, from here if you integrate and you can find the \bar{u} plus as $\int_0^y \frac{dy}{1 + \frac{\nu_t}{\nu}}$ ok. So, integrating this you can find the value of \bar{u} plus. Now, we will divide the boundary layer into two near-wall regions ok. So, if you consider flow over flat plate near to the wall; obviously, this molecular viscous force will dominate ok. And if you consider very far away from the wall then; obviously, this fluctuating component will dominate the flow.

So, due to that; obviously, the eddy viscosity will dominate the flow. So, if we divide the boundary layer into two regions very near to the wall and very far away from the wall, then you can see that here if this is the flow over a flat plate. So, this is y plus and now, if you see that very near to the wall ok this viscous force dominate. So, this is known as viscous sub layer. And if you consider away from the wall. So, let us say here it is fully turbulent zone and this region turbulent fluctuation dominate ok.

So, these are the two extreme cases you can consider and in between we can consider one overlap layer or which is known as buffer zone also, where we will have the effect of both these viscous force as well as turbulent fluctuations ok. So, now, this equation ok let us simplify for viscous sub layer and this fully turbulent layer. Now, let us consider the viscous

sub layer which is very close to the surface of the flat plate then; obviously, in this region you can see viscous sub layer dominates and the velocity fluctuations will be very small.

(Refer Slide Time: 27:08)

So, obviously, you can see that ν_t will be much much greater than ν ok. With this simplification, we can write this equation, you can see that very close to the wall viscous force dominate. So, we will get ν_t is much much smaller than ν ok. So, ν_t by ν will be much much smaller than 1. So, if it is much much smaller than 1 than, this equation we can simplify and write $\frac{\partial u^+}{\partial y^+} = 1$ ok.

So, now, if you apply the boundary conditions that at y^+ is equal to 0 u^+ is equal to 0. So, from here you can write $u^+ = y^+$ ok. And so, in the viscous sub layer region ok, we can write $u^+ = y^+$ which is a linear profile that means this $u^+ = y^+$ ok.

So, if this is the laminar sub layer or viscous sub layer, then you can see that u^+ will vary linearly with y^+ . So, if this is y^+ then you can see that here this velocity will vary linearly ok. So, this is your u^+ ok. And generally this viscous sub layer will be, in the range of $0 < y^+ \leq 7$ ok.

And, you can see that laminar sub layer is of importance for turbulent flow calculations, since the shear stress at the wall is determined by the thickness of the laminar sub layer. Now, if we consider the region far away from the wall then these viscous force will be very very small and the velocity fluctuations will dominate; that means, Reynolds stress will dominate ok.

(Refer Slide Time: 29:27)

Fully Turbulent Layer: Law of the wall

$$\left(1 + \frac{v_t}{\nu}\right) \frac{\partial u^+}{\partial y^+} = 1 \leftarrow$$

Further away from the wall, Reynolds stresses dominate

$$\nu_t \gg \nu \quad \frac{\nu_t}{\nu} \gg 1$$

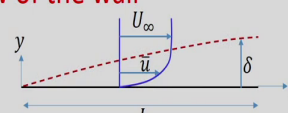

$$\frac{\nu_t}{\nu} \frac{\partial u^+}{\partial y^+} = 1$$

$$\kappa^2 y^{+2} \left(\frac{\partial u^+}{\partial y^+}\right)^2 = 1$$

$$\Rightarrow \frac{\partial u^+}{\partial y^+} = \frac{1}{\kappa y^+}$$

$$u^+ = \frac{1}{\kappa} \ln y^+ + C$$

- Law of the wall

Prandtl's mixing-length model:

$$y^+ = \frac{y u_\tau}{\nu}$$

$$u^+ = \frac{\bar{u}}{u_\tau}$$

$$\nu_t = \kappa^2 y^2 \left| \frac{\partial \bar{u}}{\partial y} \right|$$

$$\nu_t = \kappa^2 \frac{y^2 u_\tau^2}{u_\tau} \frac{\partial u^+}{\partial y^+}$$

$$\frac{\nu_t}{\nu} = \kappa^2 y^{+2} \frac{\partial u^+}{\partial y^+}$$

The constant κ is called von Karman's constant, and experimental measurements show that $\kappa \approx 0.41$. The constant of integration C can be estimated by noting that the viscous sublayer and the Law of the Wall region appear to intersect at roughly $y^+ = u^+ \sim 10.8$. Using this as a boundary condition, the integration constant is found to be $C \approx 5$.
 Thus, an approximation for the Law of the Wall region is $u^+ = 2.44 \ln y^+ + 5$

So, again we consider this equation. So, ν_t will be much much greater than ν so; obviously, you can see that in the fully turbulent layer ok far away from the wall ν_t is much much greater than ν as Reynolds stresses dominate. So, that means, ν_t by ν will be much

much greater than 1. So, from this equation, we can write $\frac{\nu_t}{\nu} \frac{du}{dy} + 1$ is equal to 1 ok.

Now, $\frac{\nu_t}{\nu}$ ok what is ν_t ? So, from Prandtl's mixing length model, we know ν_t is equal to $\kappa^2 y^2 \frac{du}{dy}$. So, we can write and we have also $\frac{du}{dy} + 1$ is equal to $\frac{y}{\nu} \tau$ and $\tau = \bar{u} \tau$ ok. So, now, $\frac{\nu_t}{\nu}$, we can write from here you can see, $\kappa^2 y^2$ ok. So, from here you can see y^2 you can write, $\frac{\nu^2}{\tau^2}$ ok.

And, we have $\frac{du}{dy}$. So, these $\frac{du}{dy}$ we can write $\frac{\tau}{\nu} \frac{du}{dy}$. So, $\frac{du}{dy} + 1$ again so, we can write $\frac{du}{dy} + 1$, but in the denominator we will have $\frac{\nu}{\tau}$ ok. In the denominator we have τ so; this will be τ^2 . So, this will get cancelled and 1 ν will be there and we can write $\frac{\nu_t}{\nu}$ as $\kappa^2 y^2 \frac{du}{dy} + 1$ ok.

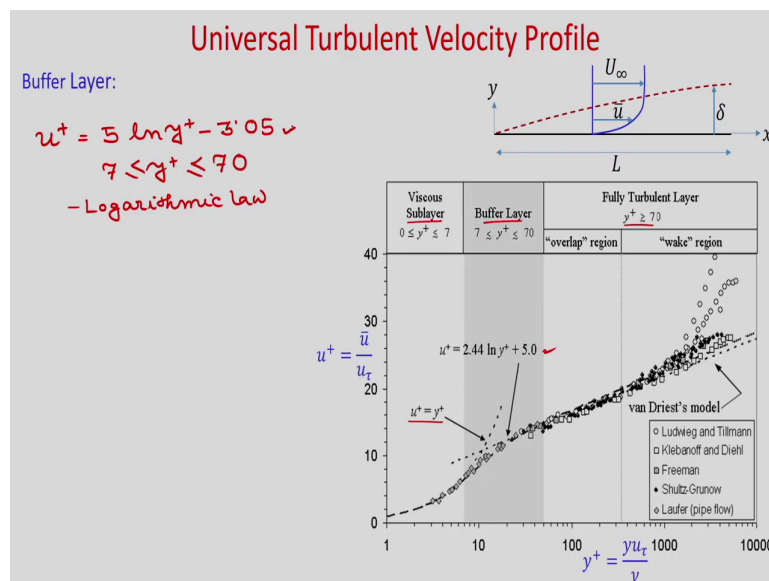

So, now, this let us write as $\kappa^2 y^2 \frac{du}{dy} + 1$ is equal to 1.

So, this we can write as $\frac{du}{dy} + 1 = \frac{1}{\kappa y}$. So, now, if we integrate this, we can write $u + y = \frac{1}{\kappa} \ln y + C$ ok. So, this is known as law of the wall ok and which is valid in fully turbulent layer. Now, what is the value of κ and C ? So, it is very difficult to determine so, these are actually determined from the experimental results ok.

So, we have some empirical relations and from there you can find the value of κ and C . This constant κ is called a Von Karman's constant and experimental measurements. So, that κ is order of 0.41 and the constant of integration C can be estimated by noting that the viscous sub layer and the law of the wall region appeared to intersect at roughly $y^+ = 10.8$. Using these as a boundary condition the integration constant is found to be 5 ok.

So, C is equal to 5. So, now, if you put kappa is equal to 0.41 and C is equal to 5, then the approximation for the law of the wall region is u^+ is equal to $2.44 \ln y^+$ plus 5. Now, we have another layer which actually in between the viscous sub layer and fully turbulent layer, that layer is known as overlap layer or buffer layer, where viscous force and the fluctuations dominate the flow. So, there are many laws proposed by different scientists.

(Refer Slide Time: 34:02)

So, we can write one of these law as u^+ is equal to $5 \ln y^+$ plus minus 3.05 and which is in the layer of $7 \leq y^+ \leq 70$ ok.

So, in this buffer layer laminar and turbulent motion coexists ok and this is your logarithmic law. You can see that y^+ up to 7, it is viscous sub layer y^+ greater than 70 it is fully turbulent layer and in between y^+ 7 and 70 we have buffer layer or overlap layer.

So, these two actually are known as overlap layer or buffer layer. Now, you can see that u^+ versus y^+ if plot. So, here this will be u^+ is equal to y^+ . So, you can see that up to $y^+ = 7$ ok, you will get almost linear profile and in fully turbulent layer. We have the logarithmic and from the experimental values different scientists they actually plotted this u^+ versus y^+ and you can see these symbols are from these results from these papers.

And we have this u^+ is equal to y^+ and we have u^+ is equal to $2.44 \ln y^+ + 5$ that is in fully turbulent layer and in between you can join and you can write this u^+ is equal to $5 \ln y^+ - 3.05$.

Turbulent Boundary Layer Equations

$$\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v} \frac{\partial \bar{u}}{\partial y} = \frac{\partial}{\partial y} \left[(\nu + \nu_t) \frac{\partial \bar{u}}{\partial y} \right]$$

$$y^+ = \frac{y u_\tau}{\nu} \quad u^+ = \frac{\bar{u}}{u_\tau} \quad u_\tau = \sqrt{\frac{\tau_w}{\rho}}$$

Viscous sublayer $y^+ < 7$
 $u^+ = y^+$

Fully turbulent layer $y^+ > 70$
 $u^+ = \frac{1}{\kappa} \ln y^+ + B$

So, now, let us summarize whatever we have studied in today's class. In today's class, we first started with the Reynolds average Navier-Stokes equations for steady state

two-dimensional flow. Using scale analysis, we have derived the turbulent boundary layer equations dropping some terms.

Then we used Prandtl's mixing length hypothesis to find the unknown minus $\rho u' v'$, but and that we have represented in terms of mixing length l . So, in the apparent shear stress, we have contribution from the molecular viscosity as well as eddy viscosity, but eddy viscosity is unknown and using Prandtl's mixing length hypothesis, we have represented this mixing length l in terms of κ and y . Finally, this eddy viscosity is represented in terms of κ and the velocity gradient.

So, obviously, we have seen that these values can be found using some experimental result in the turbulent boundary layer, we have three distinct regions, one is very near to the wall which is known as viscous sublayer or laminar sublayer, then we have far away from the wall that is known as fully turbulent layer and in between we have buffer layer or overlap layer.

So, using these non-dimensional parameters u^+ and y^+ , we have found the u^+ value in terms of y^+ in these three regions. We have seen that viscous sub layer will be y^+ from 0 to 7 and y^+ greater than 70, we have fully turbulent layer and y^+ in between 7 and 70 we have buffer layer.

Thank you.
