Lecture - 20
Problem Solving - II

Hello, I welcome you all in this course on Power Plant Engineering, today we will solve some numericals based on the lectures on the previous weeks. So, we will start with in numerical on the gas turbines ok.

(Refer Slide Time: 00:43)

A gas turbine plant consists of one turbine for compressor drive and another for output and both are having their own combustion chambers which are served by the air directly from the compressor. Air enters the compressor at 100 kPa and 15 °C and is compressed with an isentropic efficiency of 0.76. Gas inlet temperature and pressure in both turbines are 680 °C and 500 kPa. The isentropic efficiency of turbine is 0.86. The mass flow rate of air at the compressor inlet is 23 kg/s. The CV of fuel is 42 MJ/kg. Calculate the output of the plant and thermal efficiency assuming $c_p=1.005$ kJ/kg-K and $\gamma=1.4$ for air and $c_{p_g}=1.128$ kJ/kg-K and $\gamma=1.34$ for gases.

IIT ROORKEE NPTEL ONLINE CERTIFICATION COURSE Prof. RAVI KUMAR Department of Mechanical & Industrial Engineering 2

A gas turbine plant consist of one turbine for compressor drive and another for output, it means there are two turbines.

(Refer Slide Time: 00:54)

So, there is one compressor air is coming from here, after getting compressed it has two turbines. One turbine is exclusively driving this compressor, another turbine is producing the output right, so and both are having their own combustion chamber.

So, this combustion chamber one combustion chamber is here right, and another combustion chamber is also there, and from this turbine we are getting the output. Output is attained from turbine 2, and T 1 is specifically used for driving the compressor right. So, output of T 1 is going to the compressor, output of T 2 is been used by the consumer.

One combustion chamber which are served by their air directly from compressor, so the air for both the turbines or both the combustion chamber is directly coming from the combustion

chamber right. So, air is getting compressed in compressor, then air is divided in two parts; one part is going to combustion chamber of turbine which is driving the compressor.

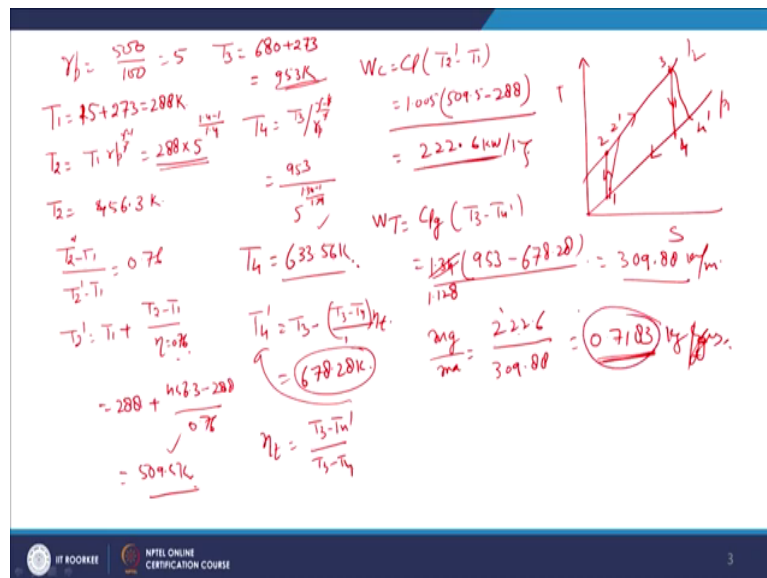

Another part of the air is going to separate combustion chamber which is driving the turbine which is giving output. The air enters the compressor at 100 kilo Pascal close to the atmosphere pressure and 15 degree centigrade temperature. Air is compressed with an isotropic efficiency of 0.76 I mean the efficiency of the compressor is 76 percent.

Gas inlet temperature and pressure in both turbines are 680 degree centigrade 500 kilo Pascal; it means at the entry level for both the turbines the temperature is same right. But, one turbine is producing only that much output which is sufficient to drive the compressor, so mass flow rate in both the turbine is not same it is different.

The isentropic efficiency of turbine is 0.86. The mass flow rate of air at compressor inlet is 23 kg per second, so it is possible out of this 23 kg 7, 8 kg is going to the turbine which is driving the compressor remaining 15, 16 kg per second is going to another turbine which is giving the output. Calorific value of fuel is 42 mega Joules per kg or 42000 kilo Joules per kg. Calculate the output of the plant and thermal efficiency; we have to calculate 2 things.

Output of the plant and thermal efficiency assuming its specific heat of the air this is specific heat of the air specific heat ratio for air. This is you can see here the specific heat of few gases spg this is specific heat of the gases. So, this is 1.128 it is higher than the specific heat of the air, because here after burning the fuel is also mixed with the air and gamma for this is also 1.34 right.

(Refer Slide Time: 04:11)

So, first of all we will draw the ah temperature entropy diagram at two pressures; pressure 1 and pressure 2; state 1 to state 2, state 2 to state 3, and 3 to 4 right. Now, the pressure ratio is given they at least from enters as compressed isentropic efficiency just 500 kilo Pascal.

So, the pressure ratio is 500 divided by 100 it is equal to 5, because r p we are going to often use. Inlet temperature T 1 is 2's sorry 15 plus 273 is equal to 288 Kelvin right. Now, we will find the value of T 2, T 2 is going to be equal to T 1 r p raise to power gamma minus 1 over gamma.

T_1 is 288, r_p is 5, $\gamma - 1$ is $1.4 - 1$ divided by 1.4, so if we solve this we are going to get the value of T_2 as 456.3 Kelvin. This is the temperature of gases at state 2, but it has certain efficiency compressor has certain efficiency of 0.76.

So, we will use the formula $T_2 - T_2$ dash sorry $T_2 - T_1$ divided by T_2 dash minus T_1 is going to be equal to 0.76 or T_2 dash is equal to T_1 plus $T_2 - T_1$ divided by efficiency that is 0.76. T_1 is known to us 288 plus $T_2 - T_1$, this is $T_2 - T_1$ that is 456.3 minus how much? 456 minus 288 divided by 0.76. And this will give us that T_2 dash is 509.5 Kelvin, so T_2 dash we have got this much.

Now, T_3 is known to us now T_3 is given here 680 degree centigrade, so 680 plus 273 it is going to be equal to 953 Kelvin. Now, we have temperatures at the state 1, state 2 dash state 3 right. Now, for a state 4 pressure T_4 again T_4 is equal to T_3 divided by r_p raise to power, now γ here the γ will come for the γ for few gases.

So, $\gamma - 1$ over γ and T_3 is 953 divided by 5 raise to power here γ is 1.34, so $1.34 - 1$ divided by 1.34 right. And this will provide the value of T_4 as 633.56 Kelvin, this is quite it high if you compare with the 2 dash it is quite high 509 and 633.56.

Now, compressor work, because compressor work has because T_4 is been taking place in two different turbines. Because, pressures are same that is why I have shown in single process otherwise this process T_3 to T_4 physically is taking place in 2 different turbines.

So, now the work of the compressor work of the compressor is for 1 kg of air we are considering only 1 kg of air. It is $C_p (T_2 - T_1)$ C_p is 1.005 for air, and T_2 dash is 509.5 minus T_1 is 288, this is work of the compressor.

And the work of the compressor is 222.6 kilowatt per kg. Now, we will go for the work of turbine, work of turbine is $C_p (T_3 - T_4)$ dash. Now, C_p of gas is 1.34 T_3 is 953 minus T_4 dash is T_4 dash you are not calculated sorry. This is calculated at T_4 dash if you

calculate T_4 is equal to T_3 minus T_3 minus T_4 divided by T_3 minus T_4 multiplied by efficiency of the compressor right.

So, this T_4 is going to be 678.28 Kelvin here also we have taken, because for this formula we have taken we are taken efficiency of the turbine is equal to T_3 minus T_4 dash divided by T_3 minus T_4 . Because, here CP_g will be cancelled out otherwise it is enthalpy at 3 minus enthalpy at 4 dash because, CP_g is getting cancelled out.

So, efficiency of the turbine is T_3 minus T_4 dash divided by T_3 minus T_4 . So, we have just manipulated here as T_4 dash as efficiency of the turbine T_3 minus T_4 T_3 minus T_4 multiplied by efficiency of the turbine and we have got this value 678. So, 678.28 Kelvin we have taken here and this gives the work of the turbine as 309.88 kg per minute, this is also per kg right.

So, mass of the gas multiplied by the mass of the air it is going to be 222.6 divided by 309.88 is equal to 0.7183 kg and this is gas this is gas. It means instead of because see the output of gas this turbine which is operating between 3 to 4 per kg of gas is this much, output of input to the compressor per kg of air is this much.

So, it means we do not have to provide the flow rate of 1 kg per second in the turbine, it has to be less than that how much less? Then we have taken the ratio. Now, if you multiply this by this one you will get this one. So, mass flow rate of the gas has to be this much, mass flow rate of the gas if you multiply this by 309 point; obviously, you are going to get this one and this much of the energy required.

So, this much amount of gas is required 1 kg of air is entering from here now what is the quantity of gas which is available at state 3? Now, quality of the gas just a minute it is it depends upon the air fuel ratio how much fuel is burnt into the?

Student: CP_g 1.128.

[FL].

Student: The CP g work out turbine is equal to specific heat of gas turbine (Refer Time: 12:29).

[FL].

Student: 1.

1.128 [FL], now here there is a correction this is this is gamma the CPg is 1.128 right this the 1.34 is gamma. So, now we have to find how much mass of fuel is being burnt per kg of air? Once you know the mass of the fuel is burnt we will get how much mass total air and mass of the fuel available at state 3 right.

(Refer Slide Time: 13:07)

Handwritten notes and a temperature-entropy (T-s) diagram illustrating a combustion process.

Energy balance equations:

$$(m_a + M_f) h_3 - M_a h_2 = M_f C_v$$

$$(1 + m_f) h_3 - h_2 = m_f C_v \rightarrow 0.01375 \text{ kg fuel/kg air}$$

$$(1 + m_f) C_p (T_3 - T_2) = m_f C_v$$

Values for the equations:

- $m_a = 1.128$
- $M_f = 0.01375$
- $M_a = 1.128$
- $C_p = 1.005$
- $C_v = 0.7183$

Calculations:

$$m_0 = 1 + m_f = 1.01375$$

$$m_0 = 1.01375 \rightarrow 0.7183 = 0.2954 \text{ kg air}$$

$$m = \frac{23 \times 0.2954 \times 1.128 (T_3 - T_2)}{2105.38 \text{ kJ}} = 2105.38 \text{ kW}$$

Thermal efficiency calculation:

$$\eta_{th} = \frac{W_{out}}{23 \times 0.01375 \times 42000} = 15.8\%$$

The T-s diagram shows a combustion process with states 1, 2, 3, and 4. The process is shown as a dashed line from state 1 to state 3, and a solid line from state 3 to state 4. The temperature (T) is on the vertical axis and entropy (s) is on the horizontal axis.

So, we will write an energy balance equation, it is mass of the air plus mass of the fuel h_3 minus mass of the air h_2 is equal to mass of the C_v . Because, again if you draw the temperature entropy diagram right, so mass of the fuel and mass of the fuel burnt here which is available at 3 right and mass of the air.

Now, here you can see mass of the air is available here if this process fuel is also added. So, enthalpy at 3 mass of the air plus mass of the fuel, mass of the air here is equal to this much heat liberated by the fuel or if you divide by mass of the air because you are assuming 1 kg of air.

So, $1 + m_f$ this will write it M , so it will be from small letter $1 + m_f h_3 - h_2$ is equal to $m_f C_v$. Now, h_3 ; now h_3 will be going to be equal to $C_p (T_3 - T_2)$

$C_p a T_2$ dash is equal to $m_f C_v$; $C_p g$ is known to us it is 1.128. So, this is 1.128 T_3 is also known to us; now the T_3 is we calculated here somewhere here no 953 right 953 Kelvin.

This is $C_p a$ is 1.005 T_2 dash also we calculated earlier, C_v is known to us 42000 kilo joules, because we are dealing in kilo Joules and kilo watt. So, 42000 kilo Joules per kg from this equation we can always find the mass of fuel burnt per kg of air. So, mass of the fuel burnt per kg of air is 0.01375 kg fuel per kg air ok.

Now, this fuel is burnt for the per kg of air, so air, so fuel few gases available for the power output. Now, this per kg of air this amount of fuel is getting mixed, so total amount of few gases is going to be 1 plus m_f is going to be equal to 1.01375 mass of the few gases.

And in previous previously we have already calculated this point 7183 of few gases will be used for power generation right. So, therefore, the mass available for output is 1.01375 minus 0.7183 is equal to 0.2954 kg per sorry 54 kg per kg of air, now we are just focusing on per kg of air right. Now, if you multiply this by the total quantity of air supplied that is 23 kg per second that is the amount of air which is sort by the compressor right.

In that case we will get the mass of the total mass of the fuel gases which are used for power generation that is 23 multiplied by 0.2954 right. And power output is going to be equal to multiplied this mass multiplied by C_p that is what is that what we are supposed to find calculate the output of the plant and thermal efficiency.

So, output is going to be the this multiplied by the $C_p g$ that is 1.128 T_3 minus T_4 dash. This is the output of the second turbine and this output is 2105.38 kilo Watt or approximately 21 mega Watt. So, in this system if there is one compressor there are two turbines; one turbine is driving the compressor another turbine is driving giving the output and the output of the turbine is this much.

For finding out the thermal efficiency this output has to be divided by input, input is 23 into 0.01375 this is mass of the fuel burnt. And multiplied by 42000 this is the calorific value of the

fuel and this thermal efficiency multiplied by of course 100, and this efficiency is coming out to be 15.8 percent.

So, in the nutshell what we have done we have simply take the system is like this the compressor has taken the air. Air is the splitting one compressor is driving the is producing sufficient power to drive the compressor one turbine is producing sufficient power to drive the compressor another turbine is giving the output.

In this system the efficiency is coming out to be 15.8 thermal efficiency is coming it is quite low. But, this is not I mean because the thermal efficiency is coming low because the maximum temperature is going up to 650 degree centigrade. If you further increase the temperature efficiency will improve, because efficiency is the gas turbine is strong function of the maximum temperature.

In any thermodynamic cycle it is a function of maximum temperature, if you look at because all the cycles are compared with the Carnot cycle. So, Carnot cycle minimum and maximum temperature that is taken into the account. So, if you keep on increasing the and in gas turbines we can go temperature higher than the steam turbines. And with the facility of pooling of modern I mean arrangement of pooling of blades very high temperature can be attained in a gas turbine right.

So, next numerical is about the leakage we have discussed in one of the lectures. So, this is the numerical as numerical are here not to just to check your computational scale it is just to give you the idea about the physical values right.

(Refer Slide Time: 20:19)

Calculate the leakage loss through the diaphragm packing in a turbine under following conditions:

Steam pressure before nozzle	14 bar ✓	
Steam superheat before nozzle	55 °C ✓	
Steam pressure after nozzle	12.5 bar ✓	
Shaft diameter	250 mm ✓	
Radial clearance	0.4 mm ✓	
Number of constriction	4 ✓	
Coefficient of contraction	0.75 ✓	

Also calculate the pressures in dwell spaces.

IT ROORKEE NPTEL ONLINE CERTIFICATION COURSE Prof. Ravi Kumar, Department of Mechanical & Industrial Engineering 3

Now, suppose there is the numerical on leakage calculate the leakage loss through a diaphragm packing in a turbine under the following condition. Steam pressure before nozzle is 14 bar steam, steam super heat steam super heat before nozzle 55 degree centigrade. Steam pressure after nozzle 12.5 bar, shaft diameter this is shaft diameter is 250 mm.

Radial clearance between the blades and the shaft is 0.4 mm, because some clearance has to be provided. So, it is not blade not blade between blade in the shaft it is housing and the blade, blade edge and the housing right. Number of constrictions as I said earlier in the previous, lecture constrictions are provided just to prevent the loss of a steam or pressure loss of a steam in it is a sort of sealing.

And constrictions are made of soft material, so that a damage of the constriction does not take place. Suppose there is a accidently there is a contact between the blade and the constriction

the damage of the blade not the constriction takes place. Sorry, the damage of constriction takes place and blade is prevented.

Now, coefficient of constriction is 0.75, the coefficient what is the coefficient? Coefficient is if you magnify this figure it is going to be like this. So, steam is passing through the restricted place space, and here also a Vena Contracta is formed. So, actual cross section area available for the transmission of fluid is less than it is only less than 75 percent right, so also calculate the pressure in dual spaces ok.

(Refer Slide Time: 22:12)

$P_1 = 14 \text{ bar}$
 $t_s = 195.04^\circ\text{C}$
 $t = 195.04 + 55 = 250.04^\circ\text{C}$
 $\rho = 0.1635 \text{ kg/m}^3$

$A_g = C_c \pi D E$
 $= 0.75 \times \pi \times 0.25 \times 0.4 \times 10^{-3}$
 $A_g = 2.356 \times 10^{-4} \text{ m}^2$

$m_{\text{max}} = 2.356 \times 10^{-4} \times \sqrt{\frac{14 - 12.52}{4 \times 14 \times 0.1635}}$
 $= 0.155 \text{ kg/s}$

$P_c = \frac{0.85 P_1}{\sqrt{2c + 15}} = \frac{0.85 \times 14 \times 10^5}{\sqrt{4 + 15}}$
 $= 5.074 \times 10^5 = 5.074 \text{ bar}$
 $P_c < P_2$

$m_{\text{max}} = A_g \sqrt{\frac{P_1^2 - P_2^2}{2c P_1 \rho}}$

$0.155 = 2.356 \times 10^{-4} \sqrt{\frac{(14 \times 10^5)^2 - (P_2 \times 10^5)^2}{2 \times 14 \times 10^5 \times 0.1635}}$
 $P_2 = 12.52 \text{ bar}$

$P_A = \sqrt{196 - 9.9152c}$
 $P_B = P_C$

So, the pressure is 14 bar right, according to this pressure the saturation temperature is 195.04 degree centigrade this we can take simply take from the steam table. Now, the superheating is 55 degree centigrade, so T is equal to 195.04 plus 55 is equal to 250.04 degree centigrade right.

Now, at this temperature we look at the super heated table and we get the specific volume also that is 0.1635 meter cube per kg. Now, area available for steam to pass that is we say it is A_g it is $C_c \pi D \epsilon$, ϵ is the clearance and here the ϵ is 0.4 mm right.

So, we will take the value of C_c as 0.75 it is already given π into diameter is 0.25 meters in this is 0.4 into 10 to power minus 3. And from here we get the area as 2.356 into 10 to power minus 4 this is the value of A_g right. Now, we will calculate the critical pressure in the last stage, so critical pressure is $0.85 p_1$ divided by $\sqrt{Z_c + 1.5}$.

Now, Z_c what is the value of Z_c here? The value of Z_c is 4 and p_1 is 14 bar. So, it is 0.85 into 14 into 10 to power 5 let us convert into the Pascal. Now, we may not, because in that case we will be getting values in Pascal otherwise if you remove this then will be getting values in bar.

So, 4 plus one point 5 and that is going to be equal to 5.074 into 10 to power 5 Pascal or 5.074 bar that is the critical pressure. Now, critical pressure is greater than p_2 sorry less than p_2 . So, critical pressure is less than p_2 , p_2 is this 12.5, so it is less than p_2 , so the steam leakage, so because you have different equations for the different conditions.

So, steam leakage will be determined by the equation is equal to $A_g \sqrt{p_1 - p_2}$ divide by $Z_c p_1 v_1$. But, A_g is known to us A_g is 2.356 into 10 to power minus 4 we have taken from here this value here A_g . Under root T_1 is 14 bar this is 12.5 bar divided by Z_c is 4 p_1 is 14 and v_1 we will take from here 0.1635 right and this mass of the leakage is going to be 0.155 kg per second.

So, this is this amount of steam which is getting leaked through the grinds right, because in when we want to improve the design in any design the estimation may be may be a rough estimation. But the estimation of all the quantities only then we can improve upon it, so here we can find 0.155 kg per second that is the amount of a steam which is been leaked out through the constrictions.

So, number of the dwell space is because they are 4 constrictions, so number of the dwell spaces is 1 2 3 3 dwell spaces, and now we have to find the pressure in each dwell spaces. So, we will use the same formula because they are all in series, so mass flow rate is going to be remain in all same in all the dwell space. Now, let us take first dwell space, so if you take the first dwell space the leakage is 1 you will use the same formula $155 \text{ to } 1.5 \text{ is equal to } 2.356$ into $10 \text{ to power minus } 4$ right. Under root $14 \text{ square minus } 12.5 \text{ square}$ and $10 \text{ to power } 5 \text{ square}$ we will take out divided by ah.

Now, this is Z_c is equal to 1, so Z_c is equal to 1, so where you are this is not 12.5 this is not 12.5 this is p_2 , because p_2 12.5 is here and 14 is here 14 bar is here 12.5 is here. So, this is p_2 pressure here, so this is not 12.5 this is p_2 and Z_c is 4 p_1 is 14 into $10 \text{ to power } 5$ and v_1 will take from here 0.1635 right and from here we will get the value of p_2 .

Because all are known only p_2 is unknown and this $10 \text{ to the power } 5$ will be cancel with this. And here we will get the value of p_2 when we are putting the Z_c is equal to 4 no sorry this is Z_c . So, p_2 is equal to under root $196 \text{ minus } 9.915 Z_c$ constrictions right. Now, we wrongly we had put 4 here we will not put 4 here, so there two unknowns p_2 and Z_c . Now, I am repeating this we have use the same formula to find the pressure inside the first constriction.

Now, pressure in the first constriction is not known 12.5 is the pressure in the last and Z_c is n is equal to 1 Z_c is 1 for here, 2 for this, 3 for this and mass leakage is known to us. So, we have found the pressure in terms of function of Z_c . Now, if you put Z_c is equal to 1 we will get p_1 this is p let us say ABC, so we will get p_A dwell space this is known as dwell space. Now, if we put p_B if you put Z_c is equal to 2 here we will get the value of p_B if you put Z_c is equal to 3 here we put we will get p_C right this is how we can get the pressures in all 3 dwell spaces.

(Refer Slide Time: 29:44)

During the test of a condenser the following readings were taken:

Barometer reading	760 mm of Hg ✓	
Condenser vacuum	700 mm of Hg ✓	
Mean Condenser temperature	35 °C ✓	
Hot well temperature	30 °C ✓	
Mass of cooling water	45000 kg/h ✓	
Intake water temp	17 °C ✓	
Outlet water temp	31 °C ✓	
Mass of condensate	1200 kg/hr ✓	

Find (a) mass of air present per unit condenser volume, (b) state of steam entering the condenser, (c) vacuum efficiency, (d) condensate under cooling and (e) condenser efficiency.

Prof. RAVI KUMAR
Department of Mechanical & Industrial Engineering

Now, there is a one short numerical on the condensers these on the condensers. During the test of the condenser the following readings were taken: barometric reading 760 it is atmospheric pressure, condenser vacuum 700 mm it means the pressure below the atmospheric pressure. So, this is 760 suppose, so pressure is somewhere here this is 700, so 760 minus 700 is the absolute pressure in the condenser, mean condenser temperature 35 degree centigrade right.

Hot because in condenser also why it is mean condenser temperature? Because inside the condenser the value temperature changes and it depends upon the presence of air with different parts of the condenser. Hot well temperature 30 degree centigrade, mass of cooling water 45000 kg per hour, intake water temperature 17 is cooling water which is used for the

condensers. Mass of condensate if this much of steam is getting condensed, mass of air present per unit condenser volume right. Now, for this we will start at 35 degree centigrade.

(Refer Slide Time: 31:01)

Handwritten calculations and diagrams:

- $$p_s = 5.629 \text{ kPa}$$
- $$P = \frac{(760 - 700)}{760} \times 1.013 \text{ bar}$$

$$= 7.997 \text{ kPa}$$
- $$p_{\text{air}} = 7.997 - 5.629$$

$$= 2.368 \text{ kPa}$$
- $$m_{\text{air}} = \frac{PV}{RT} = \frac{2.368 \times 1}{0.287 \times (273 + 35)}$$

$$= 0.02679 \text{ kg/m}^3$$
- $$Q = m_s (h_{s1} - h_{wc})$$

$$= m_s \left(\frac{h_{s1} + x h_g}{35^\circ\text{C}} - h_{wc} \right)$$

$$= 2633400 \text{ kJ/hr}$$

$$\rightarrow 1200 \text{ kg/hr}$$
- $$m_{\text{cw}} c_p \Delta T$$

$$Q = 2194.5 \text{ kW}$$
- Diagram 1: A graph showing a saturation curve with a point at 35°C on the saturation vapor line.
- Diagram 2: A schematic of a condenser showing a rectangular box with an upward arrow on the right side and a downward arrow on the left side.

What is the value of pressure? That is 5.629 kilo Pascal that is the temperature inside the condenser, so it should have this much of absolute pressure. Now, we will calculate what is the absolute pressure inside the condenser. That is 760 minus 700 divided by 760 multiplied by 1.013 into and it is going to be 7.997 kilo Pascal.

So, this pressure is greater than this one, it binds the total pressure is the partial pressure of vapor this is this plus pressure of air. So, pressure of air partial pressure of air can be found out by taking these two difference between these two. So, difference between these 2 means 7.977 minus 5.629 and this is going to be 2.368 kilo Pascal. Once the pressure of air is known

air is saturated, so not air is saturated steam is saturated, so mass of the air is equal to PV over RT .

So, now because pressure is known it can always be considered as a ideal gas. So, 2.368 into volume we can say 1 specific value R 0.287 this the value for R for air, and 273 plus 35 that is the temperature and we get 0.02679 kg per meter cube of air. Now, steam, steam is at this is hot well temperature 30 degree centigrade right.

So, here Q is equal to mass of the steam mass of the steam h_s 1 minus h_{wc} , now mass of the steam this is h_w 1 plus x lambda 1 minus h_{wc} . Now, this is at 35 degree centigrade and this is at 30 degree centigrade, you can see here the mean condenser temperature 35, hot well temperature 30 degree. It means if you look at this condensation process, so it has condensed and it is further condensed this is thirty degree centigrade hot well temperature.

From here the pump will suck the water and inside it to the boiler and this is the condenser steam temperature this is 35 degree centigrade. So, we have taken the mixture because after expansion we will get the mixture of vapor and liquid. So, we have taken property for 35 degree centigrade here and property that 30 degree centigrade here. And if you take the difference are putting the value we will be getting 2633400 kilo watts, because mass flow rate is how much 45000 kg per hour.

So, it is going to be kilo joules per hour, so it is kg per hour, so it is going be the this much kilo joules per hour. So, this is mass of the condensate this is not 45000; 45000 is mass of the cooling water, mass of the condensate is 12000.

So, this is 1200 kg per hour because mass of the steam that is mass of the condensate we have taken 12000 kg per hour that is how we are getting this value. Now, how much heat has been reviewed? That is mass of the cooling water $m c_p \Delta T$, because in the condenser the heat suppose this is the surface condenser.

So, heat removed in the condenser is mass of the cooling water $CP \Delta T$ mass of the cooling water is $CP \Delta T$ and then mass of the cooling water is known to us. CP of water is known

to us 4.2 and temperature delta T also known to us that is intake water temperature outlet water temperature. So, 31 minus 17 multiplied by specific heat of the water multiplied by 45000 divided by 3600 will give you the heat removal in kilo watts and that is coming around 2194 point 2194.5 kilo watt.

Now, this heat removal is enthalpy of this minus enthalpy at this right, and this comes out. So, from this energy balance this enthalpy at this minus enthalpy at this we will get the value of just a minute x [FL] we never knew the x here [FL].

Student: [FL].

(Refer Slide Time: 36:37)

Handwritten calculations on a whiteboard:

$$m = h_1 - h_2$$

$$Q = 1200 \times (h_f @ 35^\circ\text{C} - (h_{ws})_{35^\circ\text{C}})$$

$$45000 \times 4.18 (31 - 17) = Q$$

$$x \rightarrow 0.9$$

$$\eta = \frac{704}{76 - \frac{5029 \times 76}{101.3}} = 0.975 = 97.5\%$$

$$\eta_c = \frac{\Delta T_{\text{act}}}{\Delta T_{\text{max}}} = \frac{30 - 17}{35 - 17} = \left(\frac{14}{18}\right) 100\%$$

The whiteboard also features a small schematic diagram of a condenser with two vertical tubes, one labeled '1' and the other '2', connected at the top and bottom.

After getting the mass of the air mass of the air we will find how much heat as been extracted in the condenser right. So, this is condenser after expansion let us say this is state 1 and the

water is getting sub-cool to state 2. Because state 1 the temperature is 35 degree centigrade hot well temperature is 30 degree centigrade right.

So, we will calculate $h_1 - h_2$, h_1 is $h_f + x h_{fg}$ at 35 degree centigrade minus h_2 at 30 degree centigrade. But, here the value of x is not known and this multiplied by 12000 you will get the total amount of heat transmission, but here the value of x is not known. But, the cooling water if you look at the temperature raise of cooling water that is 17 to 31 and mass flow rate of the cooling rate is also known 45000.

So, 45000 multiplied by $4.18(31 - 17)$ will give us the heat transmission Q . Now, this value of Q if you put here we will get only unknown remains x , because these values we will get from the stream table this value will get from the stream table the only unknown remains x . And if you manipulate this values the value of x is 0.9 right, once the value of x is known.

Now, the next is we have to find is state estimating vacuum efficiency. If there is no air vacuum efficiency is 100 percent, when there is air then pressure the total pressure with the condenser is the sum of the partial pressure of air and the partial pressure of water right. So, in this case the vacuum efficiency is going to be equal to 70 divided by $76 - 5.029$ into 70 divided by into 76 divide by 101.3 . What we have done? The actual vacuum and the ideal vacuum right.

So, ideal vacuum has to be more than actual vacuum ideal vacuum when there is no air actual vacuum when there is air present in the condenser in that case absolute pressure is high. If you manipulate this value you we will be getting 0.975 or 97.5 percent this is the vacuum efficiency of the condenser right. And then last one is condenser efficiency condenser efficiency is efficiency of the condenser is actual temperature difference ideal temperature difference.

Now, the actual temperature difference is ideal temperature difference is $31 - 17$ sorry 35, because the temperature of condensing this is 35. So, it is 35 and actual is 31 only, so switch it is going to be $30 - 17$ this is actual and this is $35 - 17$. So, we are getting this is 31,

so we are getting around 14 divided by 18 multiplied by 100 this is going to be the efficiency of the condenser that is all for today.

Thank you very much.
