Burden Distribution

This lecture discusses the Burden Distribution in blast furnace.

(Refer Slide Time: 00:31)

Takeaway from this lecture are importance of the burden distribution, conventional double bell charging, bell less charging and different type of stock profile like V and M burden profile, charging sequence and the burden monitoring devices.

(Refer Slide Time: 01:07)

The slide is titled "Importance of Burden Distribution" and discusses the "Wide variation in physical properties of burden". It lists three key factors:

- > Size and shape distribution
- > Density, coefficient of friction (internal as well as external)
- > Angle of repose

A diagram on the right shows a pile of material with a blue arrow indicating the angle of repose. The slide also features a background graphic of a tree with various icons and a small inset video of a speaker in the bottom right corner.

Why should we bother about this burden distribution and what is the role of burden distribution in the performance of blast furnace operation. Burden material in blast furnace has a wide difference in size and shape distribution and also they vary widely in terms of physical properties. Therefore, it is very difficult to maintain uniform permeability across the cross-section. Here burden distribution play a major role in distributing the burden in such a way that can ensure a more uniform bed permeability across the cross section of the bed leading to effective utilization of furnace gas. Iron ore size varies from 10 to 40 millimeter; where the coke size may vary from 40 to 90 millimeter.. Shape also differ significantly; sinter is irregular in shape, pellets are spherical, coke are elliptical, lumpy ore also irregular. Iron ore is much heavier compared to the coke, approximately by 5 times.

Ore have more internal friction than coke; so ore make ridges while coke roll down; in other-words ore has high angle of repose, while coke has low angle of repose. When you lay some material on a flat surface, they make a certain angle to the horizontal making a ridge. The angle is called the angle of repose and it depends on the internal coefficient of friction. It varies from raw material to raw material and specially if raw material has wide size and shape distribution, moist, and heavy, they usually try to form a ridge with a higher angle of repose. For example, coke will have a low angle of repose and the moist, heavy iron ore with fines and wide size distribution will try to make high angle of repose. These are called the natural angle of repose and in fact in the blast furnace when

you charge material, it does not form the natural angle of repose because other factors like wall vicinity of wall, inertia from falling stream of material also influences angle of repose. So, angle of repose formed by material inside the blast furnace, may be termed as apparent angle of repose, which is also influenced by vicinity of wall and falling stream, in addition to falling stream. .

(Refer Slide Time: 05:57)

Importance of Burden Distribution
Wide variation in physical properties of burden

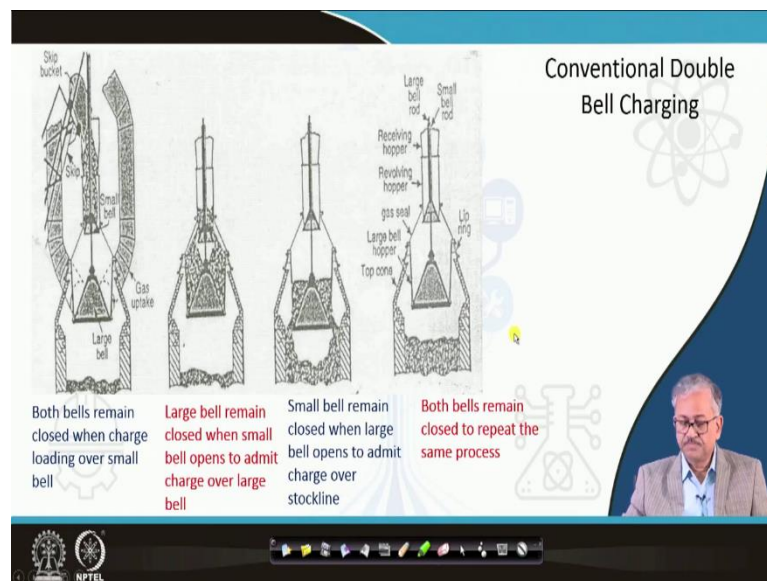

- Size and shape distribution
- Density, coefficient of friction (internal as well as external)
- Angle of repose
- Iron ores with fines tries to make ridge while bigger and lighter coke roll down the stockline.
- Lower ore to coke ratio indicate a more permeable region.

The slide features a background with a network of blue icons and a central atom symbol. A small video inset in the bottom right corner shows a man in a suit speaking. The NPTEL logo is visible in the bottom left corner.

Iron ore fines iron ore with fines tries to form a ridge; while the bigger and lighter particle like coke try to roll down the stock line. So, if coke after being laid on the stockline, those will try to roll down. So, different material after being laid on the stock line they behave differently. They either may roll down or they may try to stick to the location where they fall at the point of fall. So, as a result you can expect a lot of segregation to happen, leading to variation of ore to coke ratio from center to the periphery.

Ore to coke ratio is a very important parameter; where the ore to coke ratio is high, the region is likely to be offer more resistance to the gas flow compared to the place where the

ore to coke ratio is less; because bed with coke is permeable to gas. (Refer Slide Time: 07:29)

Let us discuss now the charging mechanism and start with conventional double bell charging.

During charge distribution, the important factors are the sequence of charging, point of fall are important to restrict segregation. Segregation does not only take place at the stock line, it initiate in the distributor also; so aim here to restrict the segregation to the maximum possible extent, which otherwise can not be eliminated totally..

There are basically 2 charging systems; one is the conventional double bell charging, and the other is recent bell less charging.

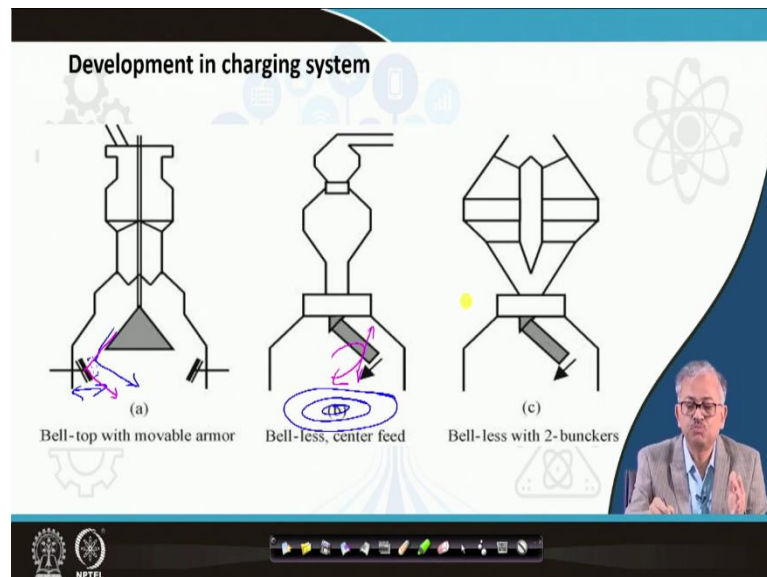

In double bell charging, you have two bells; one is the upper bell, and the other lower bell. Small bell is the upper bell and big bell is the smaller bell. How does it works? Initially both the bells are closed. By closed it means bells are up such that the gap between the wall and the bell is zero sealing any solid and gaseous movement during closed condition.

First, material are charged over the small bell directly from the skip cars. When sufficient material are charged over the upper small bell, it is lowered to allow the material to fall over the lower large bell, which remain in closed condition. When charging over lower big bell is completed, it is lowered to allow the material to be laid over the stock line in

the furnace. During big bell charging, the upper small bell is moved up to seal solid and gas passage between wall and small bell.

So, when material is charged from upper bell to lower bell, lower bell remain closed and during material charging from lower bell to stockline, the upper bell remain closed. Thus during charging operation there is no scope that blast furnace can pass through the charging device. In face blast furnace is is passed through through two uptake tubes attached from the freeboard of the stockline. Gas passage through these uptakes could be controlled through valves to control the top pressure in the blast furnace.

(Refer Slide Time: 12:27)

Now, let us see the development in the charging system. Initially we have only double bell charging. The control on charging is only limited by controlling the width of passage between the wall and the lower bell edges. If the width of passage is increase by lowering the lower bell, the material projectile will hit the stockline further away from the wall. But such control was not much effective. Besides, as the material projectile directly hit the wall, wall erosion also becomes a concern. Then came movable throat armour (MTA). It had two purposes; one thing to protect the refractory and second thing is that it can move forward and back and deflect the material at different distances away from the wall.

So, it moves forward it will deflect the material more towards the center and when it is moved backward , material will deflect less and fall near the wall. So, by moving the armor back and forth you can charge the material at different distances from the wall; of

course to a limited extent because of limitation of the width of passage between lower bell and the wall.

Now, then came the bell less charging. Here material is finally distributed by a rotating chute. It can rotate through 360o and it can also have vertical movement. So by it adjusting its vertical position, it is possible to charge material at any concentric circles across the cross section; meaning you have full access across the cross section to lay the material. The material from skip cars is first charged on the hopper and then the material moves to the chute through a down-commer and finally material is distributed on stock line through the rotating chute. Initially bell less charging was based on one hopper, when charging was intermittent. Because during charging on the hopper, discharging from chute was not possible. Then bell less charging is modified with two hoppers that makes the charging continuous.

When you have two hoppers, while you are charging one hopper; the other hopper will feed the chute that subsequently continuously feed the stockline.

(Refer Slide Time: 18:01)

Stock profiles

V Profile

- Charged near wall
- Fines forms ridge at the wall
- Coke roll down towards the axis
- Ore/coke ratio decreases towards the center
- Permeability of the bed increases towards the center
- Burden descent becomes difficult
- Chances of accretion formation at wall

The diagram shows a cross-section of a stockpile with a 'BIG BELL' at the top, a 'COKE' layer in the middle, and 'ORE' at the bottom. A speaker is visible in the bottom right corner of the slide.

Let us now discuss stock profile.. There are two kinds of stock profile. One is called the V profile another is called the M profile.

When material is laid near the wall stock forms a ridge near the wall because as we have mentioned ore does not move much and has a steep angle of repose; although the coke roll

down towards the center. The ore percentage decreases towards the center and as a result the ore/coke ratio becomes high near the wall and it decays towards the center. Consequently the stock become more permeable near the center and less permeable near the wall and gas prefers to flow through the central region. Peripheral flow becomes less. Peripheral gas flow acts as lubricant over the wall that ensure smooth descent of the burden. In absence of such peripheral flow, V stock profile obstruce the smooth descent of the burden. Besides lowe gas flow on wall reduces heat transfer to the wall and increases the temperature there, which might fuse the fines on the wall and form accretion, or scab.

Such scab formation further restricts the downward motion of the overburden. This may lead to sudden breakdown of inadequately heated solid charge to the wet zone, leading to chilling of hearth.

(Refer Slide Time: 22:57)

Stock profile- M Profile

- Charged away from wall
- Ridges form away from wall
- Coke roll down both towards center and periphery
- Ore/coke ratio maximum at the ridge and decreases both towards periphery and center
- Both peripheral and central flow is observed
- Burden descent is smooth due to peripheral flow
- Larger gas flow in the periphery is not good as it increases refractory temperature and fines fusion and accretion formation at hewall.

The diagram shows a cross-section of a blast furnace with a 'BIG BELL' at the top. Below it, a stock profile is shown with a central ridge and a smooth descent towards the walls. A small inset shows a person's face, likely the presenter.

Now, let us discuss the M profile, which is considered the better stock profile in blast furnace. Such profile is formed when material is laid on the stock line away from the wall. So, ridge will also form away from the wall, leading to a stock profile with M shape as shown above. MTA is used to deflect the material away from the wall. Although ore material forms ridge at the point of fall; coke roll down both towards the center and periphery. As a result ore coke ratio decreases from the ridge region towards both the periphery and the center. Consequently, both the central region and periphery region

becomes permeable and both central and peripheral flow can be obtained, leading to better utilization of gas. Besides, peripheral flow provides a smooth descent of the burden.

(Refer Slide Time: 26:53)

BLT Charging

- > Material can be charged in concentric circle
- > Charging may be controlled in real time based on pressure data from under burden probes

Now, let us discuss bell less charging. As we have mentioned, the rotating chute in bell less charging can lay the material in concentric circles, accessing the whole cross section of the furnace. Advantage of such charging is that you can charge permeable burden in places where flow resistance increases. During the burden descent along with chemical reaction, burden degradation and fine generation continues and the permeability of the bed evolves dynamically, which can be monitored by under burden probes measuring the pressure distribution. BLT can be coupled with the under burden probes, to identify the location of high pressure drop and rectify it by charging permeable burden like coke at those location.

(Refer Slide Time: 28:19)

Sources of segregation in the stockline

- **Charging through hopper**
 - Fines align along the feeding line and coarse along the wall
 - Discharging core draws the fines first followed by coarser particles.
- **Chute segregation**
 - Coarser and lighter particles ride up the chute. Fine and dense remain at the bottom
- **Stream segregation**
 - Heavy and regular shape objects (pellet) gives longer and compact trajectories
 - Lighter and irregular objects give small but wider trajectories.
- **Coke collapse**
 - to the center when angle of coke layer inclination > angle of internal friction. Major gas flow in the center.

The slide includes several diagrams: a hopper diagram showing fines in the center and coarse particles at the walls; a chute diagram with handwritten notes 'Rising' and 'falling' indicating particle movement; a stream segregation diagram showing different trajectories; and a coke collapse diagram showing a layer of coke on an incline.

As I have mentioned, solid segregation not only takes place at stock line; it initiates in the distributor itself. In this section we will discuss the sources of segregation in the stockline. Segregation starts at the hopper. When the material flow through the hopper, it draws the fines through the center line, where solid velocity is maximum and the coarse are aligned along the wall (see figure in the slide above). So, when the material comes out of the hopper, fines comes first followed by the coarse particles. So, some segregation is taking place in the hopper itself.

In the distributing chute also some segregation takes place. In the rotating chute, the course and lighter particles will ride up and the heavier and finer particles will stay on the bottom wall.

(Refer Slide Time: 31:13)

Sources of segregation in the stockline

- **Charging through hopper**
 - Fines align along the feeding line and coarse along the wall
 - Discharging core draws the fines first followed by coarser particles.
- **Chute segregation**
 - Coarser and lighter particles ride up the chute. Fine and dense remain at the bottom
- **Stream segregation**
 - Heavy and regular shape objects (pellet) gives longer and compact trajectories
 - Lighter and irregular objects give small but wider trajectories.
- **Coke collapse**
 - to the center when angle of coke layer inclination > angle of internal friction. Major gas flow in the center.

The slide includes a diagram of a chute with handwritten annotations: 'coarse/lighter' with an arrow pointing up the chute and 'heavy and irregular' with an arrow pointing down the chute. A small inset video shows a man speaking.

When the material will come out of the chute, those will form projectile during free fall on the stockline. The lighter and coarse particles will follow the longer path and the heavy particles will follow the shortest path (see the figure in the slide above) encompassing the wide projectile width. It may be termed as stream segregation. Then there is stockline segregation due to different angle of repose of different material, which further get aggravated being induced by falling stream and vicinity of wall. Solid percolation through the bed, ore shift and coke collapse also add to segregation. If the angle of coke on the stockline become higher than that of internal friction, coke can collapse towards the center-called the coke collapse (see figure in the slide below).

(Refer Slide Time: 32:35)

Sources of segregation in the stockline

- **Charging through hopper**
 - Fines align along the feeding line and course along the wall
 - Discharging core draws the fines first followed by coarser particles.
- **Chute segregation**
 - Coarser and lighter particles ride up the chute. Fine and dense remain at the bottom
- **Stream segregation**
 - Heavy and regular shape objects (pellet) gives longer and compact trajectories
 - Lighter and irregular objects give small but wider trajectories.
- **Coke collapse**
 - to the center when angle of coke layer inclination > angle of internal friction. Major gas flow in the center.

(Refer Slide Time: 34:03)

Charging Sequence

1. **Normal filling**
 - Charging sequence OOLCC.
 - Ore at periphery coke at the axis
 - This filling is desirable if the amount of fines is small and hence their nearness to the wall will not cause formation of accretions on the wall.
 - A lower coke rate is usually because of better peripheral utilization of CO.
2. **Reverse filling**
 - Charging sequence CCCOOL.
 - Ore rolls to the center loosening the periphery.
 - This filling makes the inwall hotter because of smaller specific heat of coke and results in higher coke rate (inferior utilization of CO).

So, now we will have talk about little bit of the charging sequence using bell charging. Charging sequence refers to the sequence of skip charging the ore, coke and the limestone. So, charging sequence OOLCC means 2 skips of ore(O) followed by one skip of limestone (L) and then two skips of coke ©.

With this charging sequence, you get the ore at the periphery and coke goes to the central region and such sequence is desirable if the amount of fines is less; otherwise fines loading

at the periphery will stop the peripheral flow, leading to lower gas utilization and unsmooth burden distribution.

And with reverse charging CCCOOL, ore will rolls to the center loosening the periphery and this filling may make the inner wall hotter. Besides, due to veru low ore to coke ratio near periphery, the large gas flow near the periphery remains mostly unutilized.

(Refer Slide Time: 36:55)

3. Mixed filling:

- Charging sequence OCOLC/CLCOC
- It is suitable for ores or sinter having a lot of fines.
- It helps in the distributions of ore both in periphery as well as in the center.
- Some of the fines are also carried to the center along with the rolling coke.

4. Separate filling:

- Charging sequence OOL/CC/C/.
- It helps loosening of the periphery.
- This filling is very suitable for closely graded material because size segregation is promoted in the method.

And then you have a mixed filling.. In this case, you charge ore only, followed by coke only. OOL/CCC means you charge two skips of ore and one skip of limestone in one go. When these material is laid on the stock line, another three skips of coke is laid over the stockline.

This charging sequence helps in loosening periphery. This filling is very suitable for closely graded material because this type of charging promote size segregation.

(Refer Slide Time: 38:37)

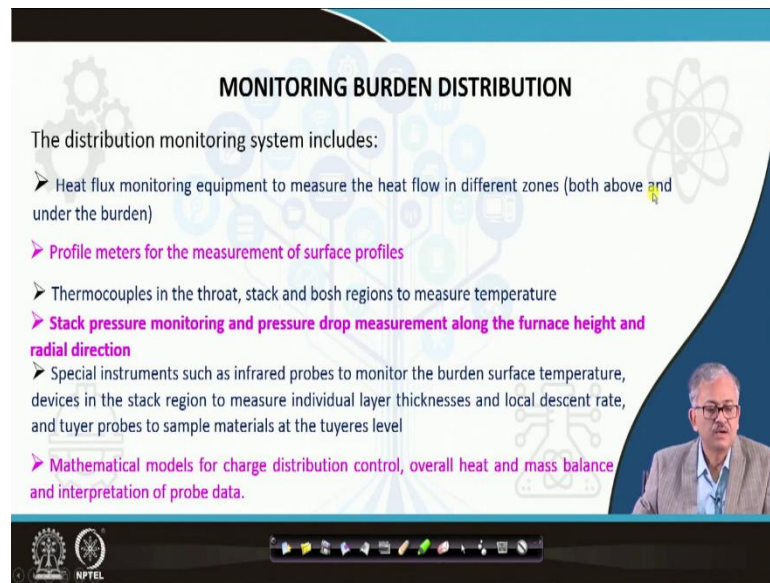

Sensitivity of charging position on ore to coke ratio

Charging Sequence	Center	Periphery
CCC7 O6 O8 CC8 C6 SnSn7	1.69	3.24
CC8 C5 O07 CC8 C5 Sn Sn7	0.91	2.75
CCC8 O5 O7 CC9 C5 SnSn8	0	2.52
CCC8 C6 O8 CC9C5Sn Sn7	0.26	4.75

Now, the table above in the slide, depicts the ore/coke ratio to the center and periphery for different charging sequence using bell less charging. CCC7O6O8CC8C6SnSn7 represents that three skip of coke is charged on 7th concentric circle (8 represents periphery and 1 center), followed by one skip ore on 6th circle followed by another skip on 8th cicle location, dfollowed by three skips of coke at 8th location, then one skip at 6th location and finally two skips of sinter at 7th location. It provides ore coke ratio in the center and periphery high, indicating better gas utilization. Higher ore to coke ration also makes the region more impervious. So, noting the value of this ratio , it is observed that center is more open to periphery.

The third sequence makes the center very open but gas utilization becomes zero in absence of ore there. Again, with the fourth sequence, periphery becomes impervious with very high ore to coke ratio.

(Refer Slide Time: 40:33)

MONITORING BURDEN DISTRIBUTION

The distribution monitoring system includes:

- Heat flux monitoring equipment to measure the heat flow in different zones (both above and under the burden)
- Profile meters for the measurement of surface profiles
- Thermocouples in the throat, stack and bosh regions to measure temperature
- Stack pressure monitoring and pressure drop measurement along the furnace height and radial direction
- Special instruments such as infrared probes to monitor the burden surface temperature, devices in the stack region to measure individual layer thicknesses and local descent rate, and tuyere probes to sample materials at the tuyeres level
- Mathematical models for charge distribution control, overall heat and mass balance and interpretation of probe data.

The slide features a background with technical icons like gears and a molecular structure. A video inset in the bottom right shows a man in a suit speaking. The NPTEL logo is visible in the bottom left corner.

Now, I will talk about the monitoring of the burden distribution in the blast furnace. We can monitor burden distribution in terms of heat flux, pressure distribution, temperature, surface profile using under burden probes.

- Profile meters are used for the measurement of surface profiles
- Thermocouples in the throat, stack and bosh regions to measure temperature
- Stack pressure monitoring and pressure drop measurement along the furnace height and radial direction
- Special instruments such as infrared probes to monitor the burden surface temperature, devices in the stack region to measure individual layer thicknesses and local descent rate, and tuyere probes to sample materials at the tuyeres level
- Mathematical models for charge distribution control, overall heat and mass balance and interpretation of probe data.

CONCLUSION

- **Burden distribution plays a crucial role in controlling the gas flow in Blast Furnace**
- There are two major stock profile in BF, namely the V-profile and M-profile
- **Removing stockline segregation is difficult to remove because it initiates in the distributor itself.**
- With the most modern Bell Less charging it is possible for real time control of bed permeability based on pressure data from underline probes

The slide features a dark blue header with the word 'CONCLUSION' in yellow. Below the header is a white area containing a bulleted list of four key points. The first and third points are highlighted in red. A small video player interface is visible at the bottom of the slide, showing a play button and a progress bar. The NPTEL logo is in the bottom left corner.

Conclusion: Burden distribution is required to make the bed more uniformly permeable across the cross section.

Two major stock profile exists, V and M profiles; and M profile provides the better bed permeability and gas utilization.

Removing stockline segregation completely is difficult as segregation starts at the distributor and continues in the stockline too.

With bell less charging it is possible for real time control of bed permeability using underburden probes.
