

NPTEL

NPTEL ONLINE CERTIFICATION COURSE

**Health, Safety & Environmental Management in
Offshore and Petroleum engineering (HSE)**

**Module 3:
Environmental issues and Management
Lecture 4: Atmospheric pollution**

Friends welcome to the fourth lecture in the module three where we are focusing on environmental issues and management that arise from drilling operations in oil and gas industries in this lecture we will focus on atmospheric pollution which arises from the drilling activities that take place or the processing activities that take place offshore and onshore in terms of oil and gas production this is a lecture given in module three in the course of HSE management in offshore and petroleum engineering at NPTEL IIT Madras.

(Refer Slide Time: 00:55)

Air pollution

- Pollutants that arise from offshore drilling are concerns of environmental impact
- environmental effects are:
 - green house effect
 - acid rain
 - smog etc.

The slide features a photograph of an industrial facility with several tall smokestacks emitting thick plumes of white smoke into the sky. In the bottom left corner, there is a small NPTEL logo consisting of three interlocking gears in red, yellow, and blue.

Air pollution is one of a very serious concern whether it is related to the process industry which comes from offshore onshore or any chemical process industries we are all aware that air pollution is a very important constraint which is bothering environmental is all over the world

friends pollutants that arise from offshore drilling have become a major concern of environmental impact because they result in various serious activities like greenhouse effect acid rain smog etc...

(Refer Slide Time: 01:28)

The slide is titled "Transport of air pollution" in a large, serif font. Below the title, it states "Mainly follows three laws:" followed by a bulleted list. The first bullet is "Mass transfer: pollutants has mass, and various analytical models use this mass to compute their transport". The second bullet is "Momentum transfer: depends on movement of pollutants" with a sub-bullet "Advection flow and wind rose diagram are useful in this case". The third bullet is "Heat transfer: depends upon lapse rate (change of temperature / increase in height)" with a sub-bullet "vertical transport is convective and results in causing heat island". In the bottom left corner, there is a small NPTEL logo. In the bottom right corner, there is a small number "3".

Transport of air pollution

- Mainly follows three laws:
 - **Mass transfer:** pollutants has mass, and various analytical models use this mass to compute their transport
 - **Momentum transfer:** depends on movement of pollutants
 - Advection flow and wind rose diagram are useful in this case
 - **Heat transfer:** depends upon lapse rate (change of temperature / increase in height)
 - vertical transport is convective and results in causing heat island

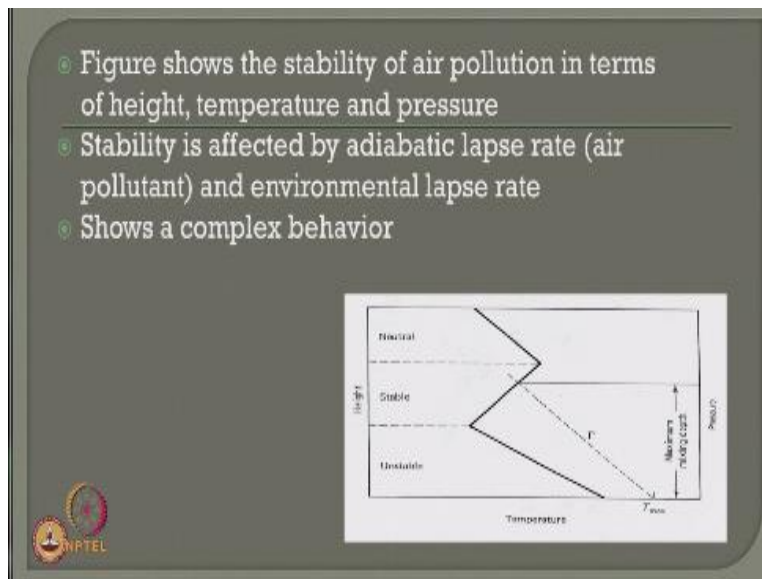

NPTEL © NPTEL- IIT Madras 3

Now a question comes whatever pollution has been caused by the drilling flora activities in offshore how are they actually transported how the society or the neighboring area in the process industry is affected, so let us talk about transport of air pollution, transport of air pollution mainly follows three laws one is the mass transfer law, the second one is the momentum transfer law, the third one is the heat transfer law.

Mass transfer law adopts pollutants having a mass and various analytical models are available in the literature which uses this mass of pollution or pollutants to compute the transport distance in terms of height and horizontal distance the momentum transfer model depends on moment of pollutants it follows advection flow wind rose diagram is very useful in this specific case of calculating the transport of air pollution when you talk about momentum transfer method.

The third method available is a heat transfer method which depends upon the lapse rate the lapse is nothing but the change of temperature with respect to increase in height so it discusses the vertical transport and shows that the vertical transport of air pollution is conducting and results in causing what we call heat island.

(Refer Slide Time: 3:00)

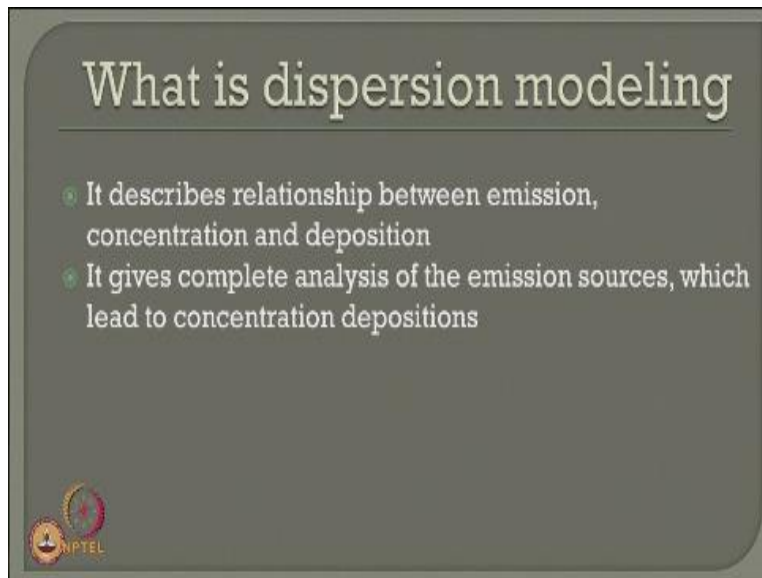

Look at the figure which is shown in this slide now this figure shows a stability of air pollution in terms of its height temperature and pressure now if you look at the x axis where temperature is plotted and look at both the y axis where one height is plotted and the other way pressure is plotted you can see that for a larger temperature for a lesser height in vertical distance the transport of air pollution becomes unstable as the temperature decreases and the height increases it is remaining stable for a specific height what we call the maximum mixing depth.

Now as the temperature further increases and the height increases you will see that they become neutral so from an unstable layer of height it gets into a neutral layer which causes the stable layer, so it is a function of temperature where as a temperature increases most of the area for low height is unstable but for a higher heights for lower temperature it is either stable or becoming neutral same story with that of the pressure as well.

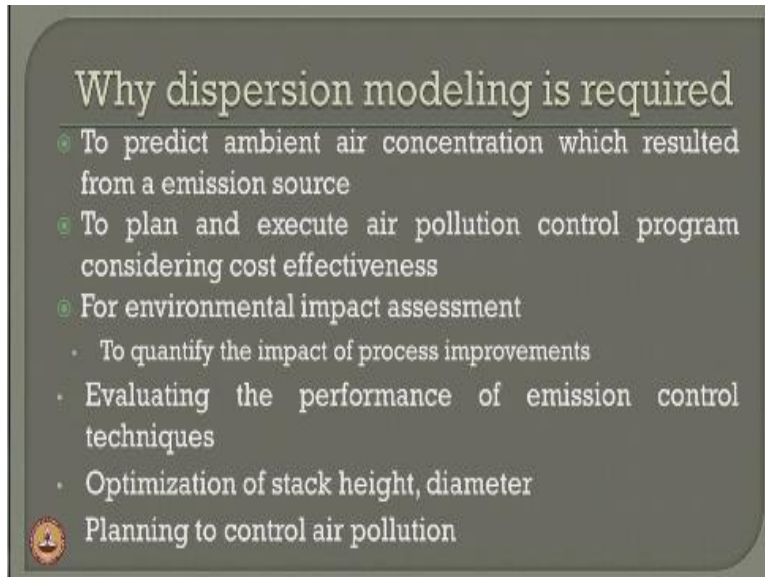

So stability is essentially affected by the adiabatic lapse rate of the air polluted and the environmental lapse rate this shows a complex behavior therefore the stability class of height distribution or the maximum mixing depth value lies in between the unstable and the neutral layer.

(Refer Slide Time: 04:40)

Now the fundamental question comes in mind is what is dispersion modeling dispersion modeling is a technique which describes the relationship between emission concentration and deposition of the pollutants it gives of course a complete analysis of the emission sources which lead to the concentration depositions.

(Refer Slide Time: 05:04)

Why dispersion modeling is required

- To predict ambient air concentration which resulted from a emission source
- To plan and execute air pollution control program considering cost effectiveness
- For environmental impact assessment
 - To quantify the impact of process improvements
 - Evaluating the performance of emission control techniques
 - Optimization of stack height, diameter
- Planning to control air pollution

One can ask a question why this dispersion modeling is required for studying air pollution models it is required because if you want to predict ambient air concentration which resulted from an emission source then one is interested looking at the dispersion models it is required to plan and execute air pollution control program which includes the cost effectiveness of the proposed programs for calculating or computing environmental impact assessment which is required to quantify the impact of process improvements dispersion models are required to evaluate the performance of emission control techniques it is also required to optimize the stack height the stack diameter of any process industry. It is of course used by enlarge in planning control air pollution.

(Refer Slide Time: 06:05)

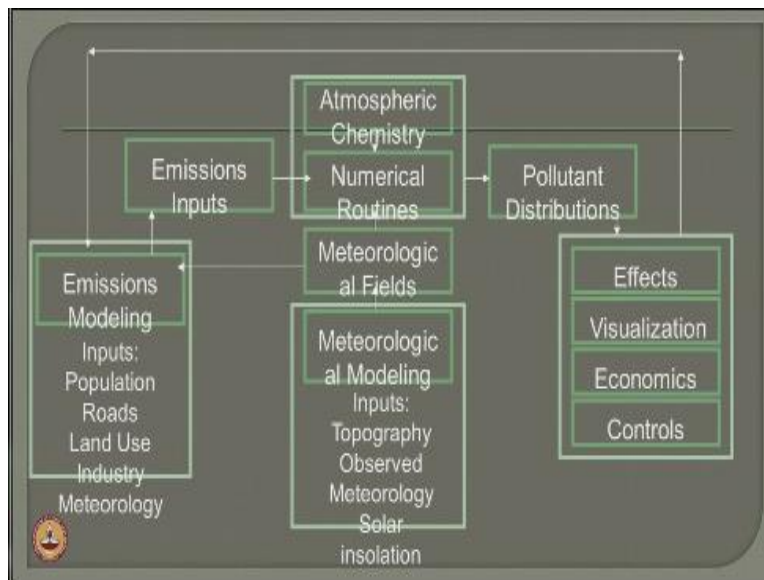

This is the very interesting cycle which discusses how the cost-benefit analysis is looped to the to that of various control options which can be seen from this figure let us say we have emissions related from any process industry there are methods analytical models which are used for either measuring them using experimental techniques or we mathematically modeling them using analytical ambient relationships they all result on how do we compute what is called exposure verse dosage a suspect and we can see from this plot very simple that as the dose keeps on increasing the adverse effect of response on the humankind or mankind is always on the exponential height.

Now one is interested no if you want to control this kind of dose response evaluation or the exposure to be limited to the mankind which arise from that of the emission occurring from the process industry then one should always see what would be the cost benefit or what is the cost investment towards controlling mission and what would be the derive benefit which is arrived from that of control programs so we call this indirectly in offshore industry as an as low as recently practical which is called as a large regions.

Once a cost-benefit analysis shows a positive result then one can go for control options and control options can be implemented and again your cost benefit analysis need to be done for the cost invested towards the control option and one should also see what is the cost investment from the control option and what is the benefit derived from the dose-response assessment so you maintain a balance between these two and then recommend of course better measurement and better control options for emission control.

However it is very interesting for us and we all accept that there is no alternative for the clean air which remains of course as a best option so a lot of natural ventilation is necessary to maintain your emission control program for a successful implementation.

(Refer Slide Time: 08:20)

This is very interesting layout of different factors which is involved in emission control program let us talk about the pollutants where we talk about atmospheric chemistry which discusses the stability class of wind the temperature humidity etc... Which are all input for a numerical routines in a given program or a software of course numerical software requires the methodological data which comes from the topography the observed data the solar isolation etc...

Once we have the data effect in the numerical program the numerical program will also give me what would be the possible or the probable distribution of the pollutants in terms of it is vertical and horizontal disbursement distances so this will tell me what will be the consequences what will be the visual effect of these kind of pollution distributions what would be economic aspects are the cost-benefit which comes from this pollution etc...

And what would be the control programs which are effective to control or to minimize the causes which is arising from the pollutant which are disbursing in the environment of course the effects of this are fed back to understand or to modify the emission modeling's which of course has inputs like population in the segment what are the various roads and land-use activity what is the industrial topography and what is the meteorological data which arise from the modification cost by the industrial pollution this specific sector.

You can see that very interestingly these two of course are interlink because you see the industry meteorology can always affected or input by the topography of the ground or the layout of the plant or the city so you have this data interconnector to the emission modeling then you give emission inputs to the numerical model so it is a very interesting closed loop program where the data from the meteorological modeling which includes emission details are becoming input to the model which receives atmospheric chemistry from the meteorological data gives me output of course output is fed back again to cause the effects caused by the emission and there is a closed loop.

So as long as we do not get a very interesting cost-benefit and economics on the control programs of pollution distributions the program is not and cannot be successfully implemented.

(Refer Slide Time: 10:50)

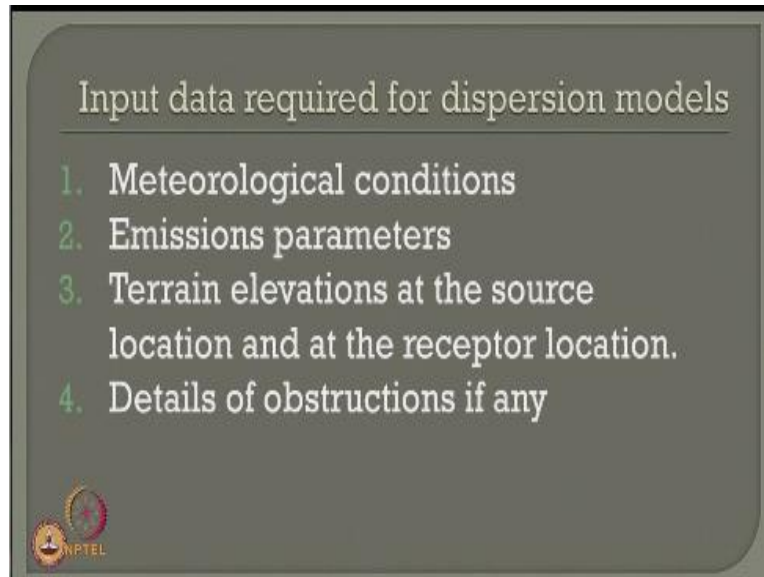

Basics of air pollution dispersion models

- All air pollution models are based on the simple Material Balance Principles
- The general material balance equation for a air pollution model can be written as follows:

$$\text{Accumulation Rate} = (\text{All flow rates in}) - (\text{All flow rates out}) + (\text{Creation rate}) - (\text{Destruction Rate})$$

Let us quickly see what are the different basics of air pollution dispersion models all air pollution models are essentially based on simple material balance principles the general material balance equation for an air pollution can be given by the relationship as accumulation rate in the environment is nothing but the sum of all flow rates coming into the environment minus or flow rates getting out of the environment plus the creation rate minus the destruction rate so it is nothing but an algebraic sum of the inflow coming into the environment in terms of the flow rates coming from the pollutants the creation rate and the exit from the environment in terms of the flow rates and the destruction cost by the pollutants in the environment.

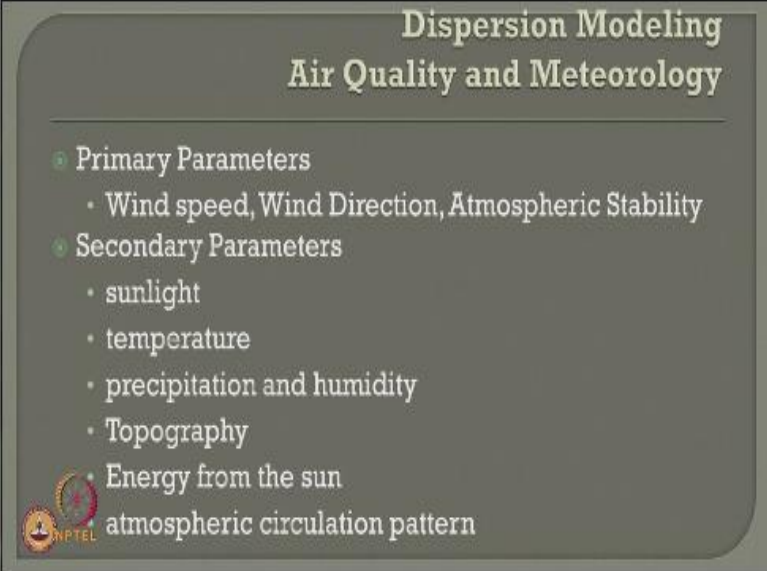

(Refer Slide Time: 11:42)

Now one can ask me a question what are all the input data required for computing dispersion models we must of course require the detail meteorological conditions available in specific location one should also have what are the different emission parameters that arise from industrial model one should also look at the terrain elevations because these elevation can cause what is called ground center concentration while working out the dispersion models one should also look at the source location and the receptor location geography and geometry. One should also have details of any obstructions in terms of toiletries taller buildings etc...

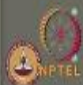

If you really wanted to calculate what will be the effect of the consequence arising from the pollution dispersion in the atmosphere.

(Refer Slide Time: 12:34)

Dispersion Modeling
Air Quality and Meteorology

- Primary Parameters
 - Wind speed, Wind Direction, Atmospheric Stability
- Secondary Parameters
 - sunlight
 - temperature
 - precipitation and humidity
 - Topography
 - Energy from the sun
 - atmospheric circulation pattern

Let us talk about air quality and meteorology details in dispersion models the primary parameters which are required to do air quality management could be the wind speed the wind direction and atmospheric stability class which are locally applied to a specific location there are various secondary parameters which are also important to compute air quality management sunlight temperature precipitation and humidity in the local area the topography of the area energy received from the sunlight in terms of natural ventilation and of course one is interested to know the atmospheric circulation pattern which can be seen from the wind rose diagrams of a specific location.

(Refer Slide Time: 13:17)

Stability

- Dry adiabatic lapse rate: temperature decreases due to lower pressure (ideal gas law)

$$\Gamma = -\frac{dT}{dz} = -1.00 \text{ } ^\circ\text{C}/100 \text{ m} = -5.4 \text{ } ^\circ\text{F} / 1000 \text{ ft}$$

- $< \Gamma$ (temperature falls faster) unstable or super-adiabatic
- $> \Gamma$ (temperature falls slower) stable or sub-adiabatic
- $= \Gamma$ (same rate) neutral

If you talk about stability class of environment the dry adiabatic lapse rate is one of the important factor which governs the stability class it shows that the temperature decreases generally due to lower pressure which follows an ideal gas law however ambient actual lapse rate depends on the factor γ where γ is given by the equation as in the slide now which is nothing but the differentials but to height which is minus 1 degree Celsius for every hundred meters or -5.4 degree Fahrenheit for every thousand feet.

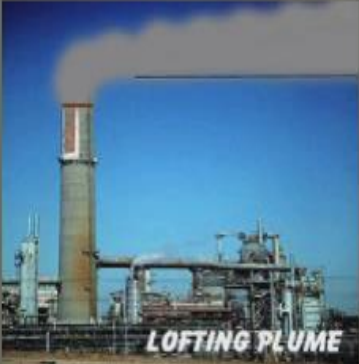

So if the temperature falls if the temperature or the lapse rate is lesser than the γ value computed then it is understood that the temperature falls faster which results in what we call unstable class or it is a call super adiabatic condition if that adiabatic lapse rate is more than γ computer from this equation then one can infer that the temperature falls slower are it addresses a stable class which is called sub adiabatic condition on the other hand if the adiabatic lapse rate is exactly equal to the γ computer from this equation. Then one can say that it belongs to a neutral stability class.

(Refer Slide Time: 14:44)

Plume behavior

Lofting Plume

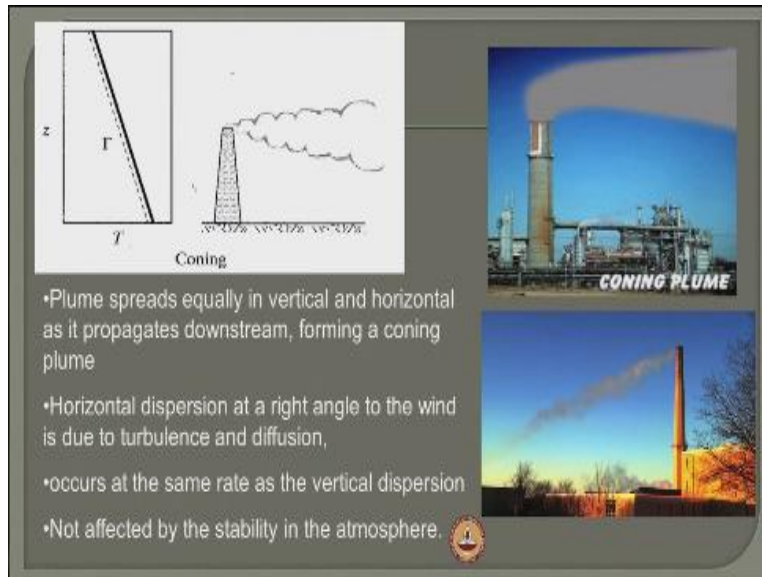

- causes impacts at ground level.
- Pollutants go up into environment.
- They are created when atmospheric conditions are unstable above the plume and stable below.

13

One important factor which arise from that of the emissions caused by the process industry in the environment is what we call plumes there are different kinds of plumes let us see one by one slowly what do we understand the a plume behavior the foremost plume which comes from a stack of a processing industry which is a refinery industry can be what we call the lofting plume lofting plume causes seviour impacts at the ground level pollutants actually go up into the environment they are created when the atmospheric conditions are unstable above the plume and stable below the plume.

(Refer Slide Time: 15:26)

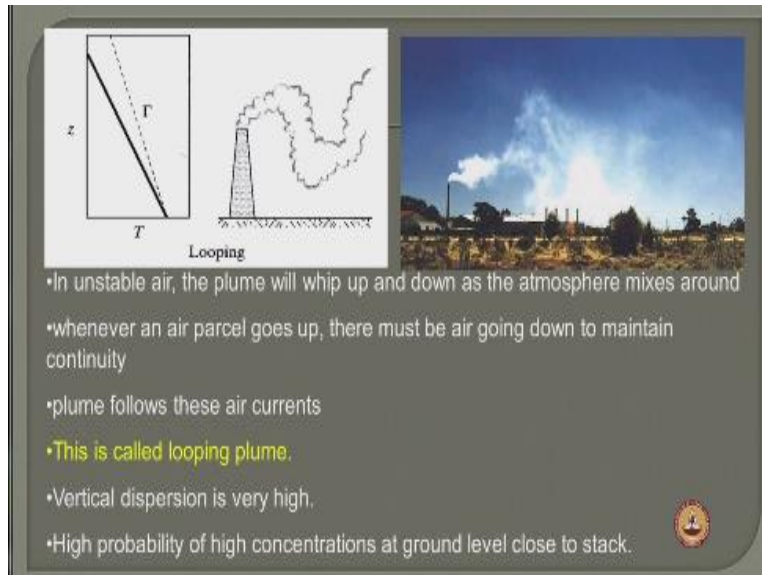

Coning

- Plume spreads equally in vertical and horizontal as it propagates downstream, forming a coning plume
- Horizontal dispersion at a right angle to the wind is due to turbulence and diffusion,
- occurs at the same rate as the vertical dispersion
- Not affected by the stability in the atmosphere.

The second effect caused by the plume is called the coning plume. The coning effect is very interesting to understand. The plume spreads equally both in horizontal and vertical direction as it propagates downstream. It forms a cone as you see in the photograph and the numerical model on the screen now. The horizontal dispersion is actually happening at right angle to the wind direction, which is due to the turbulence and diffusion. It occurs at the same rate as that of the vertical dispersion. It is not affected by the stability in the atmosphere at all.

(Refer Slide Time: 16:05)

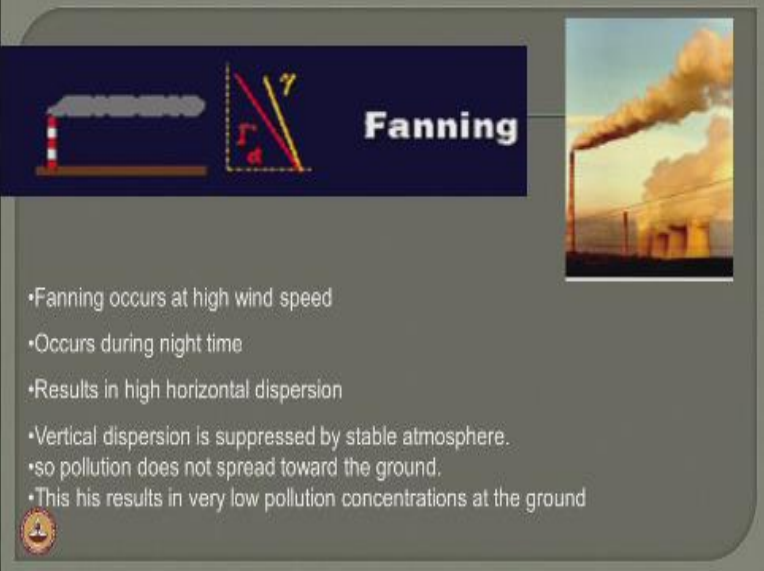

Looping

- In unstable air, the plume will whip up and down as the atmosphere mixes around
- whenever an air parcel goes up, there must be air going down to maintain continuity
- plume follows these air currents
- This is called looping plume.
- Vertical dispersion is very high.
- High probability of high concentrations at ground level close to stack.

The third affect what we call is a looping plume in an unstable air the plume will whip up and down as the atmosphere mixes around when the air parcel goes up naturally there must be an air coming down to maintain continuity and the plume follows these air currents we can see here the plume which is coming from the stack follows an up and down movement this is what we call as looping plume this call is as a looping plume the vertical dispersion arising from the spoon is very high it has a high probability of more concentration at the ground level close to the stack.

You can see very interestingly here looping plume model which comes out from a stack of a Industry.

(Refer Slide Time: 16:56)

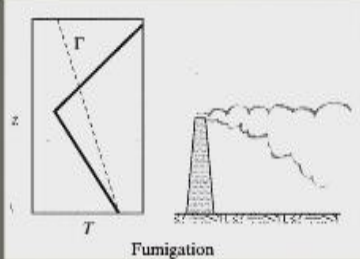

Fanning

- Fanning occurs at high wind speed
- Occurs during night time
- Results in high horizontal dispersion
- Vertical dispersion is suppressed by stable atmosphere.
- so pollution does not spread toward the ground.
- This his results in very low pollution concentrations at the ground

The next type of plume behavior is identified as fanning behavior in the literature Fanning occurs when the wind speed is very high in a specific locality generally fanning occurs during the night time it results in a very high horizontal dispersion of the pollutant in the air the vertical dispersion of course is suppressed by the stable atmosphere so the pollution does not spread towards the ground this results in a very rare pollution concentration at the ground.

(Refer Slide Time: 17:28)

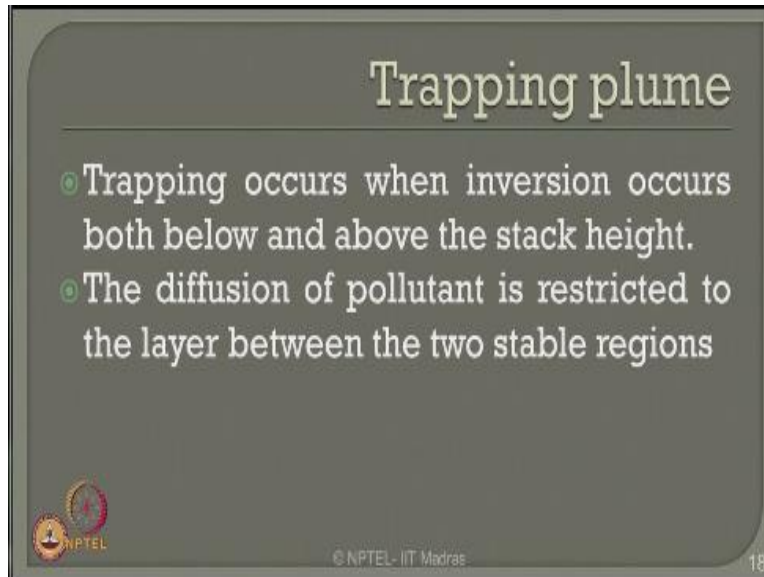

Fumigation:
Most dangerous plume
Contaminants are all coming down to ground level.
They are created when atmospheric conditions are inversion stable above the plume and unstable below.
This happens most often after the daylight sun has warmed the atmosphere, which turns a night time fanning plume into fumigation

The next effect which comes from the air pollution arising from the stack of a process industry is what we call fumigation it is the most dangerous Plume the contaminants are all coming down to the ground level directly as you see in this photograph they are created when the atmospheric conditions are in motion stable above the plume and unstable below the plume this happens most often after the daylight sun has warmed up the atmosphere which turns a night time Fanning plume into fumigation.

(Refer Slide Time: 18: 04)

The slide features a dark grey background with a light grey border. At the top right, the title 'Trapping plume' is written in a serif font. Below the title, two bullet points are listed, each starting with a small green circle. The first bullet point reads 'Trapping occurs when inversion occurs both below and above the stack height.' The second bullet point reads 'The diffusion of pollutant is restricted to the layer between the two stable regions'. In the bottom left corner, there are two circular logos: one for NPTEL (National Programme on Technology Enhanced Learning) and another for IIT Madras. In the bottom center, the text '© NPTEL- IIT Madras' is visible, and in the bottom right corner, the number '18' is displayed.

Trapping plume

- Trapping occurs when inversion occurs both below and above the stack height.
- The diffusion of pollutant is restricted to the layer between the two stable regions

© NPTEL- IIT Madras 18

There is something called a trapping plume which is seen in the atmosphere trapping occurs when inversion occurs both below and above the stack height the diffusion of pollutant is restricted to the layer between the two stable regions in a given system.

(Refer Slide Time: 18:21)

Neutral plume

- It tends to rise vertically until it reaches air density similar to that of plume itself.
- It is often converted to coning if wind velocity is greater than 10 m/sec
- It also occurs when cloud cover blocks solar radiation.

© NPTEL - IIT Madras 19

Say something called a neutral plume which tends to rise vertically until it reaches air density similar to that of plume itself it is often converted to a coning plume if the wind velocity is greater than 10 meter per second it also occurs when cloud covers blocks the solar radiation.

(Refer Slide Time: 18:42)

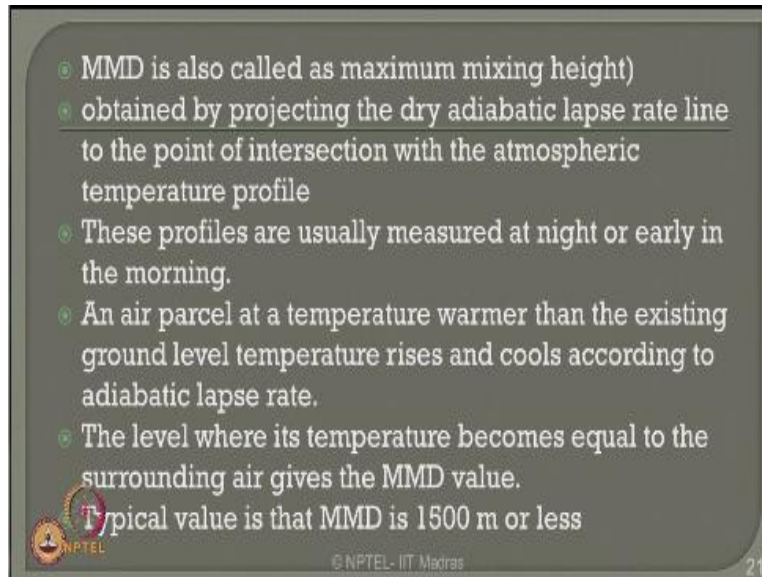

Maximum mixing depth

- Dispersion of pollutants in lower atmosphere is aided by convective and turbulent mixing.
- Vertical extent of this mixing depends on environmental lapse rate
 - affected by topographical features.
- Depth of convective mixing layer in which vertical movement of pollutants is possible is called maximum mixing depth (MMD).

 © NPTEL- IIT Madras 20

One is interested to know it is air pollution model what is called MMD which stands for maximum mixing depth the dispersion of pollutants in lower atmosphere is generally aided by conducting and turbulent mixture the vertical extent of this mixing depends on the environmental lapse rate which is also affected by topographical features in a given location the depth of convective mixing layer in which vertical movement of pollutants is possible is what we call as maximum mixing depth I will give you the next slide how to compute this particular distance or the depth.

(Refer Slide Time: 19:20)

• MMD is also called as maximum mixing height)

• obtained by projecting the dry adiabatic lapse rate line to the point of intersection with the atmospheric temperature profile

• These profiles are usually measured at night or early in the morning.

• An air parcel at a temperature warmer than the existing ground level temperature rises and cools according to adiabatic lapse rate.

• The level where its temperature becomes equal to the surrounding air gives the MMD value.

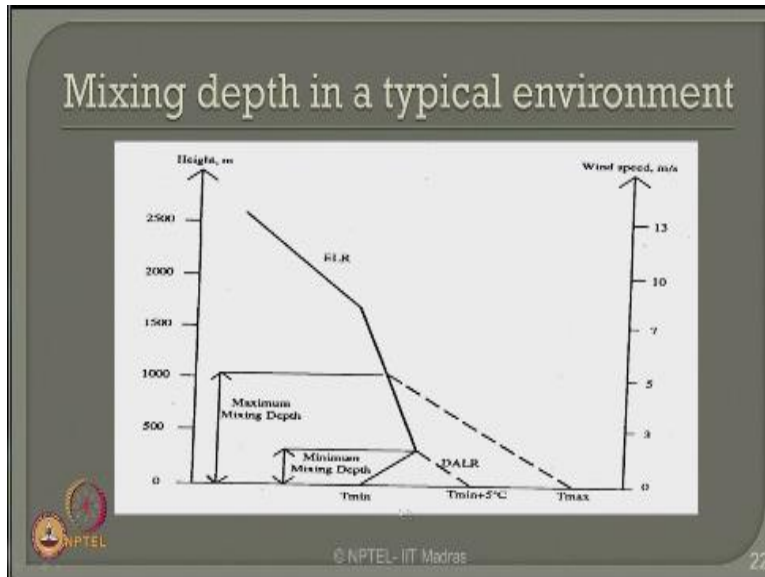

• Typical value is that MMD is 1500 m or less

 © NPTEL- IIT Madras 21

Maximum mixing depth is also called as maximum mixing height it is obtained the projecting the dry adiabatic lapse rate line to that of the point of intersection with atmospheric temperature profile these profiles are usually measured at night or early in the morning and air parcel at a temperature warmer than existing ground level temperature rises and then subsequently cools according to the adiabatic lapse rate the level where it is temperature becomes equal exactly to the surrounding air gives me the maximum mixing depth value.

The typical value of maximum mixing depth in the literature is about thousand five hundred meters or slightly lesser than this.

(Refer Slide Time: 20:08)

The mixing depth in a typical environment looks like this a mixing depth actually is a function of temperature height and wind speed one is interested to know what would be the influence of temperature on the maximum mixing depth in terms of height and in terms of mixing in the wind speed in meter per second so look at the temperature minimum it can cause a minimum mixing deep closely about that is a 300 to 400 meters where the wind speed is from 2 to 3 meter per second.

Even at a lower temperature as a temperature keeps on increasing to the maximum wind height or a temperature which is five degree centigrade plus the minimum temperature the maximum mixing depth increases to as high as thousand meters where the velocity of wind is at a rate of about five to six meter per second so the mixing depth depends on the temperature and of course the wind velocity and the stability class of the wind speed at a specific location.

(Refer Slide Time: 21:18)

Determination of maximum mixing height

- ◆ The following steps are used:
 1. Plot the temperature profile (ELR) of a day
 2. Plot the maximum surface temperature for the day on the graph for morning
 3. Draw a dry adiabatic line ($-1^{\circ}\text{C}/100\text{m}$) from the point of maximum surface temperature to the point where it intersects the morning temperature profile.
 4. Read the corresponding height above ground at the point of intersection obtained in step 2.
 5. This is the maximum mixing height for the day.

© NPTEL- IIT Madras  23

Now the question comes how to determine the maximum mixing height or the maximum mixing depth for a given site there are different steps involved in doing this calculation step number one plot the temperature profile of a day which we call ELR plot the maximum surface temperature for the day on the graph for the morning temperature draw a dry adiabatic line the dry adiabatic line governing is given by minus 1 degree centigrade for every hundred meter you have to draw this line from the point of maximum surface temperature to a point where it intersects the morning temperature profile read the corresponding height above the ground at a part of intersection obtained instep number two and that will give me the maximum mixing height for the specific day.

(Refer Slide Time: 22:10)

Temperature Inversion

- Temperature inversion occurs when a layer of warmer air covers the colder air at ground level
- It forms when the ground level air is kept cold by the cold ground.
- When warm air mass enters the area and covers the cold air, inversion acts like a lid over the cold ground level air

NPTEL © NPTEL - IIT Madras 24

The temperature inversion is another serious problem which is actually a different philosophy in terms of air pollution temperature inversion occurs in the layer of warm air covers the colder air at a ground level it forms when the ground level air is kept colder by the colder ground when warm air mass enters the area and covers the cold air content inversion acts like a lid over a cold ground level air.

(Refer Slide Time: 22:40)

Look at this figure where in a normal situation generally hot air rises and the cooler is trapped between the coldest possible and the hot air and we all know as hot rise it is colder so a normal situation whereas for the temperature inversion occurs you will see that the colder it is re circulated and the inversion layer or the warmer layer trapped between the two cold layer therefore it does not escape through this is trapped and this what we call as temperature inversion.

(Refer Slide Time: 23:15)

The temperature inversion can cause a very different environment to that of the species and an air class which actually covers a cloud layer of different temperature over a colder ground because of the heat retention in the colder area.

(Refer Slide Time: 23:34)

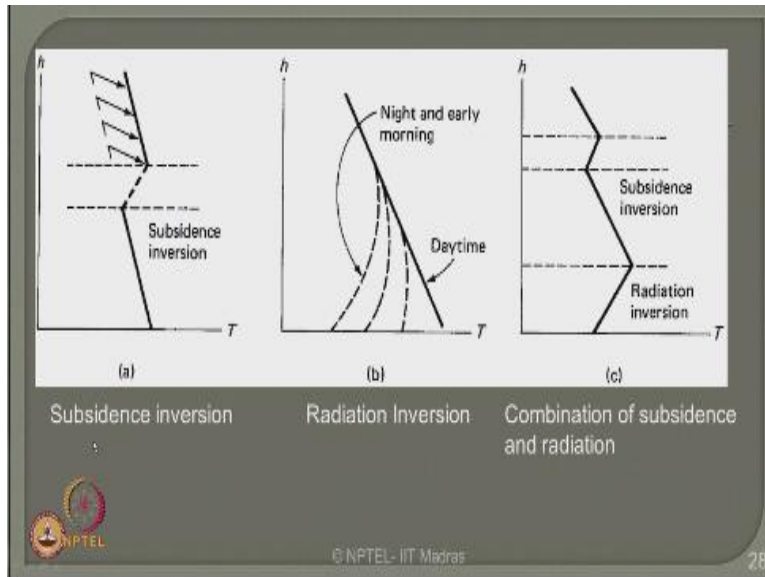

Inversion

- Inversion is defined as increase in temperature with respect to altitude
- It is also known as negative lapse rate.
- Major types of inversion:
 1. Subsidence Inversion
 2. Radiation Inversion
 3. Combination of subsidence and radiation

© NPTEL- IIT Madras 27

Inversion actually therefore is defined as an increase in temperature with respect to altitude it will also known as negative lapse rate in the literature there are major types of inversion which are seen in the literature as subsidence inversion radiation inversion and a combination of these two let us see one by one quickly and briefly.

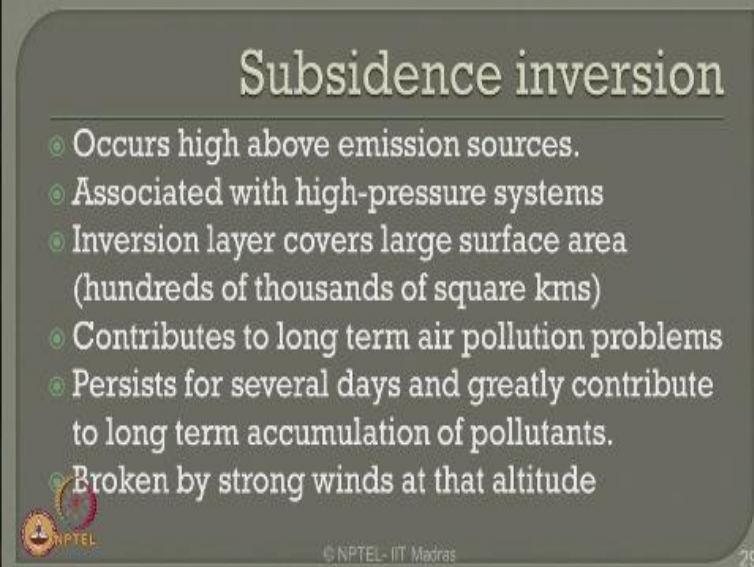

(Refer Slide Time: 23:56)

The subsidence inversion is actually occurring at a specific temperature which decreases with increase in height then increases marginally then further decreases with increase in height whereas the radiation inversion is having a constant value where the decrease in temperature causes increase in height but not as linear as it was in the case of subsidence inversion model so the change and drawn at the maximum point of these will give me a curve which we will talk about the temperature during the day time.

Whereas the combination of these two of course will be a complex model where it has got a linear and none any technology is arising from the of what you see in between the layer here as you see in the case of subsidence inversion.

(Refer Slide Time: 25:50)

Subsidence inversion

- ◊ Occurs high above emission sources.
- ◊ Associated with high-pressure systems
- ◊ Inversion layer covers large surface area (hundreds of thousands of square kms)
- ◊ Contributes to long term air pollution problems
- ◊ Persists for several days and greatly contribute to long term accumulation of pollutants.
- ◊ Broken by strong winds at that altitude

 © NPTEL- IIT Madras 29

Subsidence inversion generally occurs high above the emission sources it is associated with high pressure systems the inversion layer covers large surface area especially this can be seen in literature as hundreds of thousands of square kilometers it contributes your long term air pollution problems that is a very serious difficulty as well subsidence inversion is concerned it persists for several days and can contribute to long-term accumulation of pollutants in the environment. Of course it is broken by strong winds at a very high altitude.

(Refer Slide Time: 25:26)

The elevation of the base of inversion takes place which varies from 200 meters to the that of thousand meters, so that is the inversion layer which can vary from a height of altitude about 200 to 1000 meters and it is trapped between the two layer as you see in this case and I will show you how the wind directions allow the pollution transport takes place in inversion layer so they are actually trapped between this the subsidizing air which gets mixed completely in the colder region.

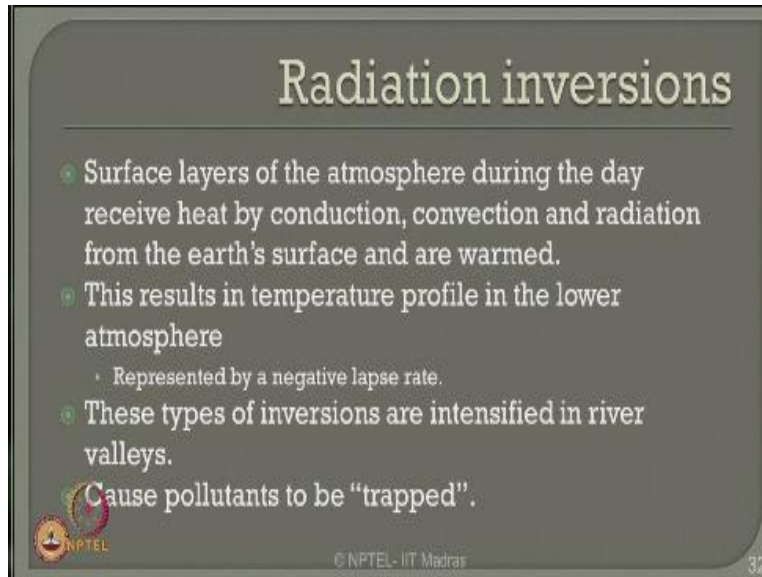

(Refer Slide Time: 25:57)

This figure shows that how the decreasing temperature results in increasing altitude as you see from the linear line here which is one of the important effect which is caused by the mixing in the atmosphere if the mixing can be locked during inversion layer you see this is where actually the decrease in temperature with increasing altitude get trapped and that becomes an inversion layer.

So the warmer air is located here whereas this becomes a colder one and there is a circle with cycle happening in this inversion layer which is actually called as a mixing blocked pollution trap beneath the inversion and this is where the pollution cannot be escaped out and it does not depend are result in vertical dispersion.

(Refer Slide Time: 26:46)

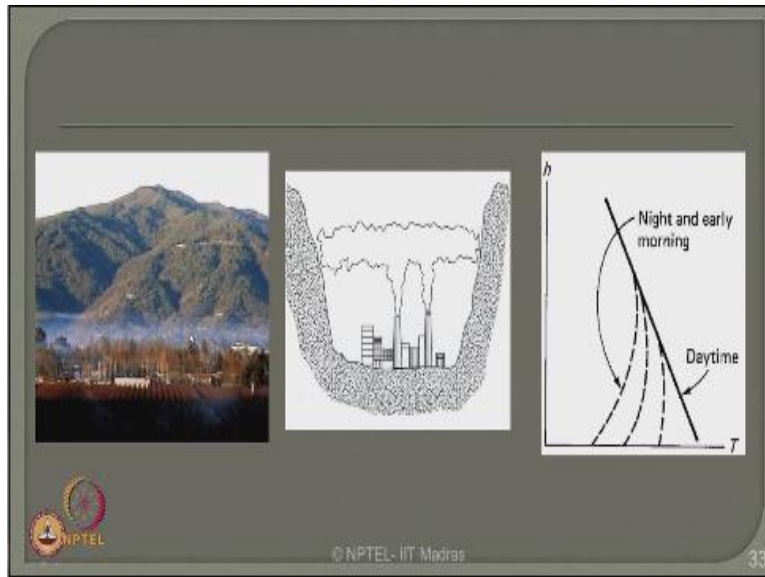

Radiation inversions

- Surface layers of the atmosphere during the day receive heat by conduction, convection and radiation from the earth's surface and are warmed.
- This results in temperature profile in the lower atmosphere
 - Represented by a negative lapse rate.
- These types of inversions are intensified in river valleys.
Cause pollutants to be "trapped".

 © NPTEL - IIT Madras 32

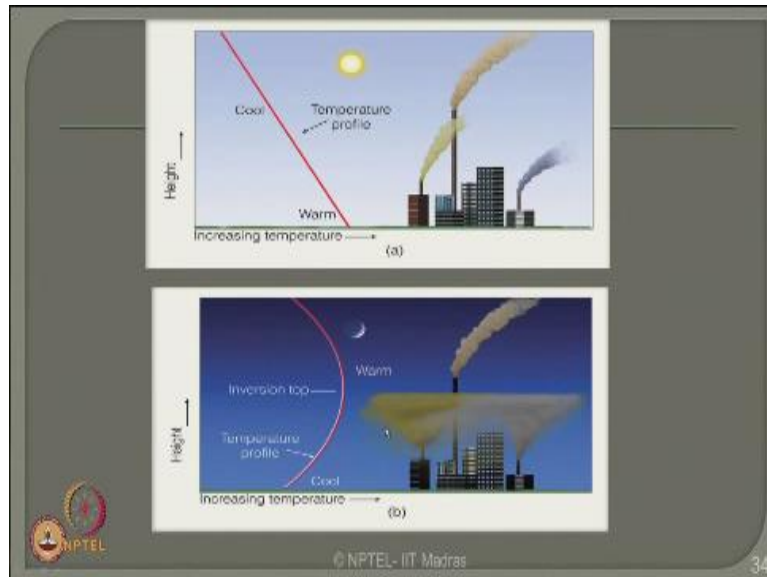

Now the radiation inversions caused by the air pollution when the surface layers are atmosphere during the day receives heat by conduction convection and radiation from the earth surface and are warm radiation innovations occur in the environment this results in temperature profile in the lower atmosphere which is represented by a negative lapse rate these types of inversions are intensified in river valleys in general it causes pollutants to be trapped between the inversion layers as we saw in the last slide.

(Refer Slide Time: 27:21)

So you can see here the river valleys is very interesting that these pollutions actually trap they do not get escape and they cause serious damage to the environment as well as to the mankind because of the effects caused by this pollution in terms of its contamination this is a very interesting model which already discussed and they say clear photograph shows how this pollution is actually trapped between the segment's in a three-dimensional view in a valley.

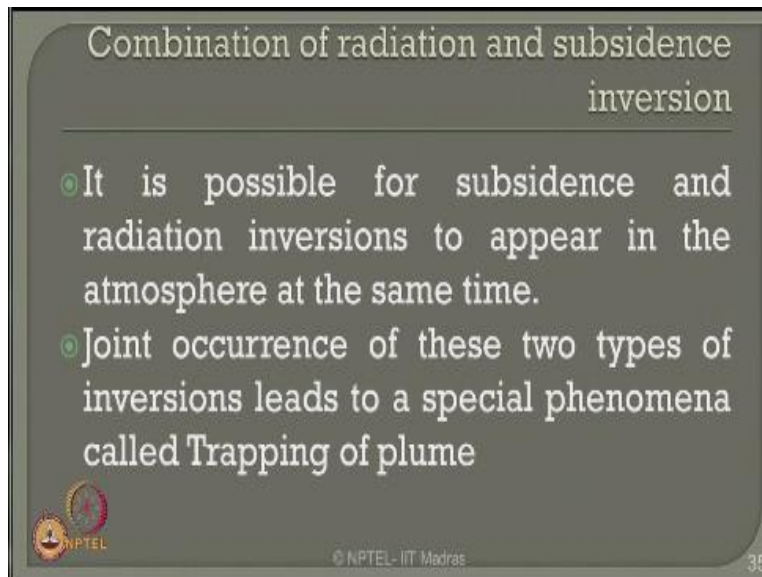

(Refer Slide Time: 27:49)

If you look at increase in temperature expect to height you can always see that there is a normal temperature profile or located the closest segment in this as it goes up it becomes cool and the temperature profile shows that there is a decrease in temperature as you keep on increasing the height whereas in case of inversion it happens the other way where the temperature increases as increase the height and then it decreases as it height is increased.

So there is an inversion layer which happens which actually traps the pollution without allowing it further dispersing in the atmosphere and this is the effect which we call as clouding effect which causes lot of serious contaminations to air pollution near the stacks of the process industry.

(Refer Slide Time: 28:40)

Combination of radiation and subsidence inversion

- It is possible for subsidence and radiation inversions to appear in the atmosphere at the same time.
- Joint occurrence of these two types of inversions leads to a special phenomena called Trapping of plume

 © NPTEL- IIT Madras 35

If you look at the combination of radiation subsidence inversions we subsequently happen in many cases it is possible for subsidence in radiation inversions to appear in the atmosphere simultaneously the joint occurrence of these two types of inversion actually leads to special phenomena called trapping of the plume.

(Refer Slide Time: 28:57)

The slide features a dark grey background with a light grey border. At the top, the title "Unified Dispersion Model" is written in a serif font. Below the title, there is a list of five bullet points, each starting with a green circular icon. The first bullet point is "Used for consequence and risk studies". The second is "For two-phase pressurized release, it calculates the dispersion in downwind direction", with a sub-bullet point below it: "Calculates the touching down point". The third is "Applicable to toxic and flammable releases". The fourth is "After touchdown point, it assumes uniform surface roughness". In the bottom left corner, there is a small logo for NPTEL (National Programme on Technology Enhanced Learning) featuring a lamp and the text "NPTEL". In the bottom center, it says "© NPTEL - IIT Madras". In the bottom right corner, the number "36" is displayed.

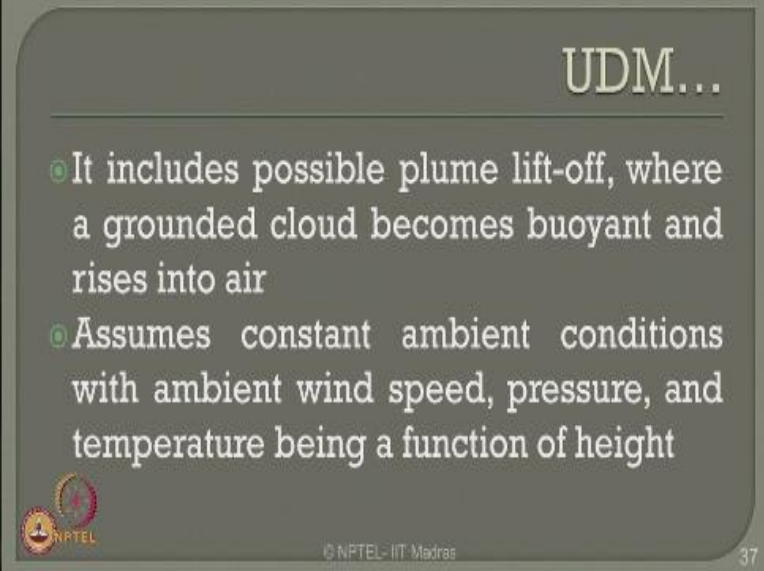

Unified Dispersion Model

- Used for consequence and risk studies
- For two-phase pressurized release, it calculates the dispersion in downwind direction
 - Calculates the touching down point
- Applicable to toxic and flammable releases
- After touchdown point, it assumes uniform surface roughness

© NPTEL - IIT Madras 36

One can also look at the unified dispersion model which can characterize this kind of dispersion releases in the atmosphere. It is used for consequence and risk studies for two-phase pressurized release. It calculates dispersion downward direction. It calculates what is called touching down point in a given plume. It is applicable to toxic and flammable release models in the atmospheric pollution studies. After the touch stone point is reached in the ground, it assumes a uniform surface roughness.

(Refer Slide Time: 29:30)

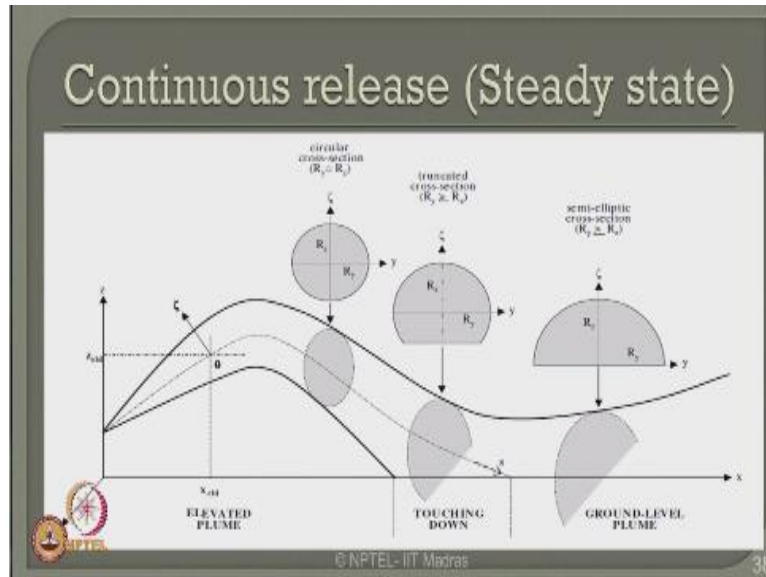

UDM...

- It includes possible plume lift-off, where a grounded cloud becomes buoyant and rises into air
- Assumes constant ambient conditions with ambient wind speed, pressure, and temperature being a function of height

 © NPTEL - IIT Madras 37

If you looked at the models it includes possible plume liftoff where a grounded cloud becomes buoyant and further rises into the atmosphere it assumes constant ambient condition with ambient wind speed pressure and temperature being a function of the height.

(Refer Slide Time: 29:50)

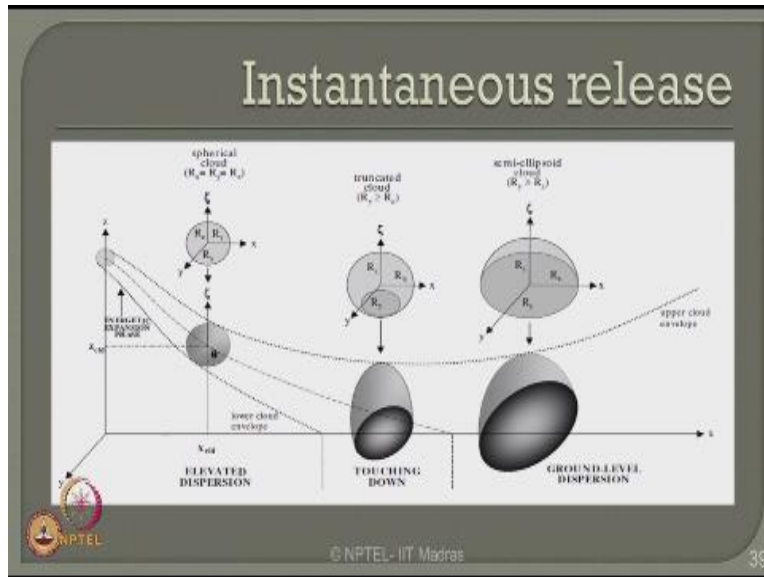

So if you look at the continuous release which is called a steady state release of Plume in the atmosphere so this is what we call as an altitude height of the cloud Z cloud and the angle $Zeta$ from a point of theta from the X cloud is we because an elevator plume so initially the plume is elevated a specific point then the plume settles down and the point by the plume touches the ground is what we call the touching down point.

There is always a probability that the touching down point maybe at one location where X can be computed and depending upon the plume diameter and density you will see that it can be either a circular cross section where $R_y = R_z$, R_y is measured in this axis and Z is measured in this axis can be equal forming a plume can be also a truncated cross section where $R_y > R_z$ R_y can become a semi elliptical where R_y is significantly as an R_z I as seen in this case.

So in such situation this becomes the area the volume of concentration of the plume which affects environment which is actually the horizontal dispersion distance of the occurrence of the plume in terms of its X axis as well as Y and as well as the vertical dispersion in the atmosphere we call this kind of model as continuous release model or steady state model.

(Refer Slide Time: 31:20)

One can also look at instantaneous release of the model let us say have a plume at a specific location Z cloud which is indicated here which is released instantaneously and this can be plume which can travel along the x-axis of course along the Y and of course along the Z-axis but unfortunately as it keeps on traveling X you will see that that the touch stone point is reached and then it picks off and if further travels in horizontal ground level dispersion.

In such cases the distribution of this plume towards the ground level touch point becomes either truncated or semi ellipsoid unlike in case of ellipse or circular in the earlier case of steady state release.

(Refer Slide Time: 32:02)

UDM

- The Cartesian co-ordinates x, y, z represents downwind, crosswind and vertical directions
- $X=0$; corresponds to point of release
- $Y=0$; corresponds to plume centre line
- $Z=0$; corresponds to ground level
- Cloud co-ordinates are given by s & ζ
- s is the arc length measured along plume centre with $s=0$ corresponding to point of release

NPTEL IIT Madras 40

Therefore, the cartesian coordinates of x, y, z of this kind of plume distribution or dispersion along x, y and z axis represents the downward the crosswind and the vertical directions respectively x is equal to 0 corresponds release of the plume y equals 0 corresponds to plume centerline and z equal 0 corresponds the ground level in all these figures what I showed you in the last couple of slides.

The cloud coordinate therefore are given by s and zeta where s is the arc length measured along the plume center with s is equal to 0 corresponding to a point of release of this plume from the point of release from the ground.

UDM...

- In case of steady state dispersion, the co-ordinate ζ indicates the direction perpendicular to the plume centre line
- The angle between the plume centre line and the horizontal is denoted by $\theta = \theta(s)$
- Vertical plume height above the ground is indicated by $z_{\text{cld}} = z_{\text{cld}}(s)$
- z is given by the relation

$$z = z_{\text{cld}} + \zeta \cos\theta$$

 © NPTEL - IIT Madras 41

In case of steady state dispersion the coordinate Zeta indicates the direction of perpendicularity to the plume centerline the angle between the plume center line and the Horizontal is denoted by θ also called as θs in literature the vertical plume height above the ground is indicated by Z_{cloud} which is now given by a simple relationship that $Z_{\text{cloud}} + Zeta \cos\theta$ will give it a Z by any relation of the plume from the height in the vertical axis.

(Refer Slide Time: 33:23)

UDM....

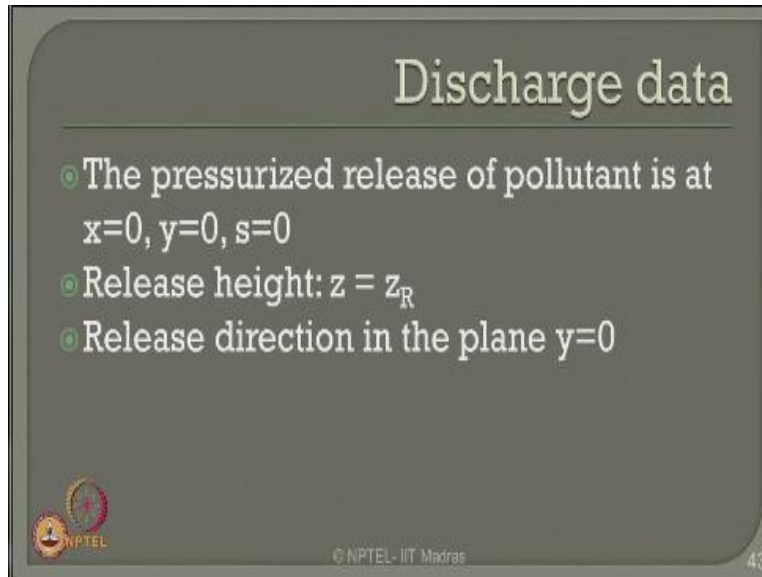

- For instantaneous release, the co-ordinate ζ indicates the vertical distance above the plume centre line and perpendicular to the y direction
- The angle between plume centre line and horizontal is denoted as θ and the vertical plume height above ground by z_{cld}
- Therefore z is given by the relation:

$$z = z_{\text{cld}} + \zeta$$

© NPTEL - IIT Madras 42

For instantaneous models the coordinate Zeta indicates the vertical distance above the plume center line and it is perpendicular to the Y direction the angle between the plume center line and horizontal is denoted as θ and the vertical plume height above the ground is given by Z cloud and therefore Z in this case is given by a simple relation where Z is given by Z cloud plus zeta.

Discharge data

- The pressurized release of pollutant is at $x=0, y=0, s=0$
- Release height: $z = z_R$
- Release direction in the plane $y=0$

 © NPTEL- IIT Madras 43

When we talk about the discharge data which is arising from the plume dispersion along x y and z axis respectively the pressure is release of pollutant in the atmosphere is specifically occurring at a specific location at x, y, s all the three set to zero the release height z is given by an equation which is equal to z_R where the release direction in the plane is given by a value where y is set to 0.

(Refer Slide Time: 34:20)

We will talk about the release models more in detail which can give me the z_R value for various factors affecting the plume dispersion in the x y and z directions respectively so in this lecture friends we discussed about the atmospheric pollution caused by the dispersion occurring from the plume formation which occurs from a vertical stack of any process industry we have seen different models we have seen different kinds of plumes which occur we have also out how the touch turning point can be calculated and how the vertical cloud distance can be computed and you have very seriously understood what is called the inversion which suppresses the dispersion of this plume or the concentration air pollution in around the stack where the pollution or the pollutant is released into the atmosphere thank you very much.
