Lecture - 03
Rotational Motion – III

In the previous lectures we saw how we apply the concept of angular momentum to solve rigid body problems. We mainly focused on conservation of angular momentum for body is moving about a fix axis. In this lecture we are going to start with the motion when an external torque on a body is applied.

(Refer Slide Time: 00:55)

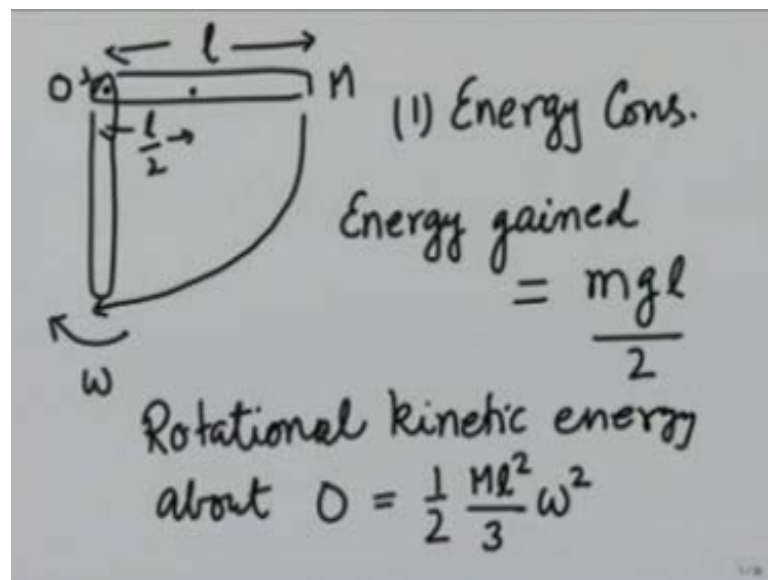

For example let me show you. I will take this scale and hold it on horizontal position like this.

(Refer Slide Time: 01:10)

Leave it, take on horizontal position and leave it. What I would like to know is when it reaches here ignoring friction what is this angular speed. So, the problem that I am solving is I have a scale like this.

(Refer Slide Time: 01:23)

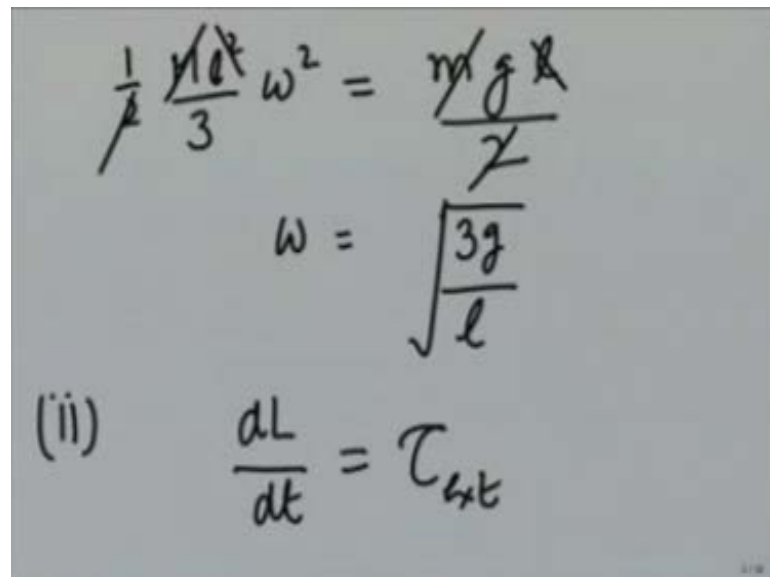

It can rotate about this point O for example, and when we leave it, it drops down like this. I would like to know what is this angular speed omega, when it comes here. I will solve this problem in 2 ways show you what a wrong way. So, let the length of the scale

be l . So, that the center of mass is at $l/2$ if it is a uniform scale. Let this mass be M . So, first let me apply energy conservation right away.

When the scale falls its center of mass drops down by a height of $l/2$. So, the energy gained should be equal to $m g l$ divided by 2. All of this energy gets transformed into its kinetic energy which in this case is the rotational kinetic energy. Energy about point O this is point O, I remind you and this is going to be equal to $1/2 I$ about point O which you see in the previous lecture is $M l^2$ over 3 times ω^2 . The 2 should be equal.

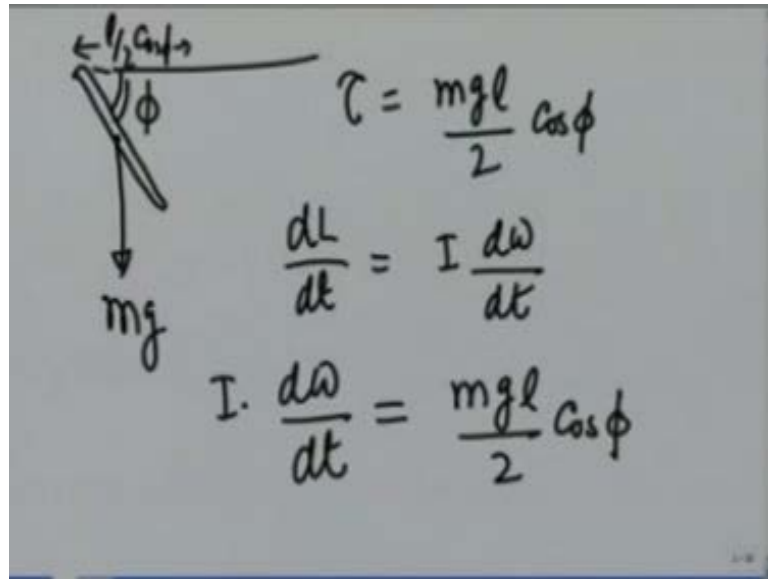

(Refer Slide Time: 03:16)

The image shows handwritten mathematical equations on a grey background. The first equation is $\frac{1}{2} \frac{M l^2}{3} \omega^2 = \frac{m g l}{2}$. Below it is the solution for ω : $\omega = \sqrt{\frac{3g}{l}}$. Below that is the equation $(ii) \quad \frac{dL}{dt} = \tau_{ext}$.

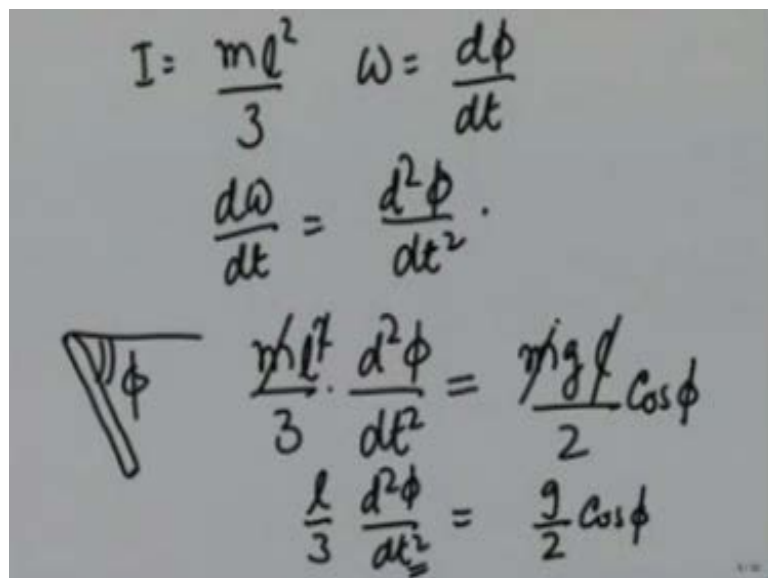

Therefore, I have $1/2 M l^2 \omega^2 / 3$ is equal to $M g l / 2$. This M cancels this 2 cancels 1 of the l 's cancels. Therefore, I get ω equals $3g$ over l square root. So, this is the answer that comes off energy conservation. Second way is by applying the equation that dL/dt is equal to external torque and let us apply that.

(Refer Slide Time: 04:02)

Let the position of the rod be at an angle ϕ from the horizontal. At that point all the force acts here mg and therefore, the torque that is being applied is going to be equal to $m g l$ divided by 2, cosine of ϕ because this distance is l over 2 cosine of ϕ . This should be equal to $d L d t$ which is nothing but I about point $O d \omega d t$. Therefore, I should have I which is moment of inertia $d \omega$ over $d t$ is equal to $m g l$ divided by 2 cosine of ϕ .

(Refer Slide Time: 05:06)

As I already have mentioned I is ml^2 over 3 ω is $d\phi$ over dt . Therefore, $d\omega$ over dt is $d^2\phi$ over dt^2 and therefore, the equation when the rod is at an angle ϕ from the horizontal is going to be ml^2 over 3 $d^2\phi$ over dt^2 , which is $I\alpha$ or I times the angular acceleration is equal to mg over 2 cosine of ϕ . L cancels m cancels and therefore, I get l over 3 $d^2\phi$ over dt^2 is equal to g over 2 cosine of ϕ . Since the left hand side involves t , we will use an old trick that we have used earlier in deriving energy conservation.

(Refer Slide Time: 06:21)

$$\frac{d^2\phi}{dt^2} = \frac{d}{dt} \left(\frac{d\phi}{dt} \right) = \frac{d}{d\phi} \left(\frac{d\phi}{dt} \right) \cdot \left(\frac{d\phi}{dt} \right)$$

$$= \frac{1}{2} \frac{d}{d\phi} (\dot{\phi}^2)$$

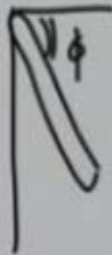

$$\frac{ml^2}{3} \frac{1}{2} \frac{d}{d\phi} (\dot{\phi}^2) = \frac{mgl}{2} \cos\phi$$

$$\frac{d}{d\phi} \dot{\phi}^2 = 3g \cos\phi$$

That is to write $d^2\phi$ over dt^2 as d over dt of $d\phi$ over dt which is nothing but d over $d\phi$ of $d\phi$ over dt times $d\phi$ over dt which can be written as $1/2$ of d over $d\phi$ of $\dot{\phi}^2$ which is $d\dot{\phi}^2$ over dt^2 . Therefore, the earlier equation becomes $1/2$ d over $d\phi$ $\dot{\phi}^2$ which is nothing but $d^2\phi$ over dt^2 is equal to mg over 2 cosine ϕ . There was, I here which is ml^2 over 3 .

I had simplified earlier I will do it again m cancels this 2 cancels 1 of the l 's cancels. Therefore, I get d over $d\phi$ of $\dot{\phi}^2$ is equal to $3g$ cosine of ϕ .

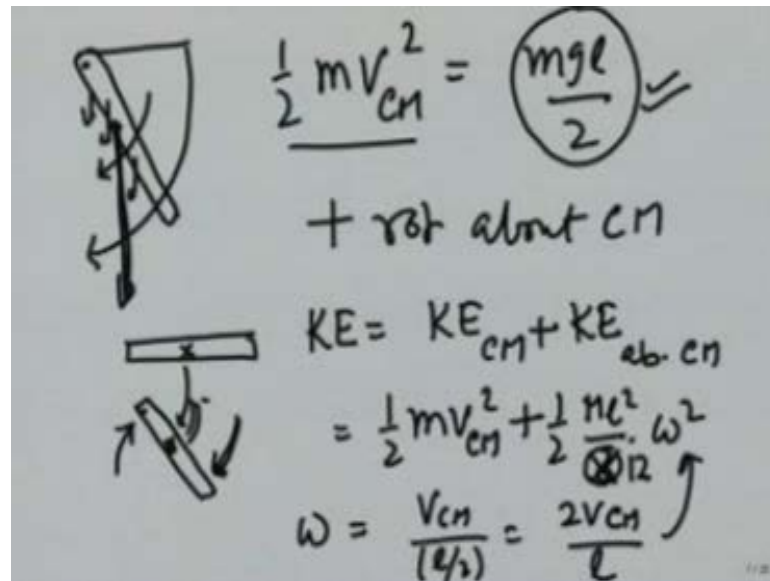

(Refer Slide Time: 07:44)

$$l \frac{d\dot{\phi}^2}{d\phi} = 3g \cos\phi$$
$$\Rightarrow l \dot{\phi}^2 = 3g \sin\phi \Big|_0^{\pi/2}$$
$$\Rightarrow \dot{\phi}^2 = \left(\frac{3g}{l} \right)$$

Therefore, integrating which is $d\phi \dot{\phi}^2$ equals $3g \cos\phi$. There is an l also here. So, I can write l here this is for a rod which is of length l and this angle is ϕ . This gives you $l \dot{\phi}^2$ is equal to $3g \sin\phi$ starting from 0 to angle $\pi/2$ when it comes to the vertical. This gives you $\dot{\phi}^2$ equal $3g/l$ which is the same answer as obtained earlier.

So, I have used energy conservation directly and I have also integrated the equation of motion, which essentially by this transformation comes to energy conservation law energy conservation by itself. Now, you may ask at this point.

(Refer Slide Time: 08:39)

Why did not I do one more thing why could not I do that $\frac{1}{2} m v_{CM}^2$ is equal to $mgl/2$ when the rod came from here to here. After all it is the center of mass which is moving and it moves with a speed v_{CM} and this should be equal to the gained gain energy because the potential energy drop what is wrong with this. What is not here is that you have to be careful when there are extended bodies involved, when velocities are distributed over the body when forces are distributed over the body that what all is happening.

For example here if I start with this position here is the center of mass when the rod comes in this position, not only has the center of mass moved. You see with respect to the center of mass the body has also rotated like this. So, in coming down like this the scale is performing 2 motions. The center of mass is moving and the scale as you can see is changing it is orientation with respect to an axis passing through the center of mass. It is rotating and it is rotating exactly by the same angle, as it was rotating about O.

So, actually the motion is $\frac{1}{2} m v_{CM}^2$ plus rotation about C M. If you calculate the kinetic energy it is always KE of CM plus KE about CM, it will come out to be $\frac{1}{2} m v_{CM}^2$ plus $\frac{1}{2} I_{CM} \omega^2$ which will be $\frac{M l^2}{12} \omega^2$. Omega by definition here is going to be v_{CM} divided by $l/2$ which is $2 v_{CM}$ divided by l , about center of mass should be $\frac{1}{12} M l^2$ about it is $\frac{1}{3} M l^2$ about CM it is $\frac{1}{12} M l^2$.

If you substitute these numbers and you get precisely the answer that you got earlier. What you may ask at this point is, but what about the torque. Torque the forces are also distributed, but I took torque to be acting at the CM because the torque depends linearly on the distance from the pivot point. Its average comes out to be as if it is acting on the center of mass, but not when I calculate the moment of the velocity because that becomes r times r omega it depends on it as r square.

So, you have to be careful when we are talking about rigid bodies and distribution of forces and velocity over the body, that we take proper consideration of rotation and angular momentum also. As an extended example of this let me now take just booklet.

(Refer Slide Time: 11:53)

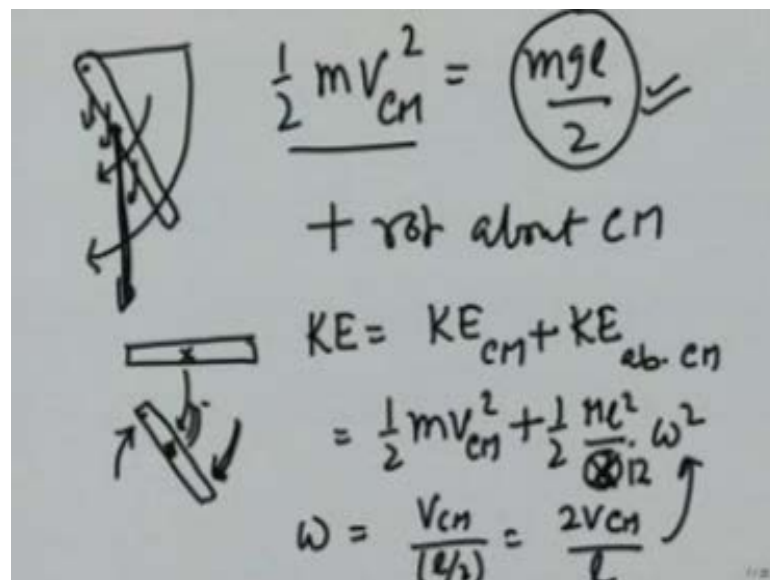

I will keep its printed side on top.

(Refer Slide Time: 11:57)

Drop it I will keep the printed side on top and drop it you see the printed side has gone down. Let me do it again I am keeping the printed side up dropping it roughly from 1 meter and let us see what happens the printed side goes down.

(Refer Slide Time: 12:19)

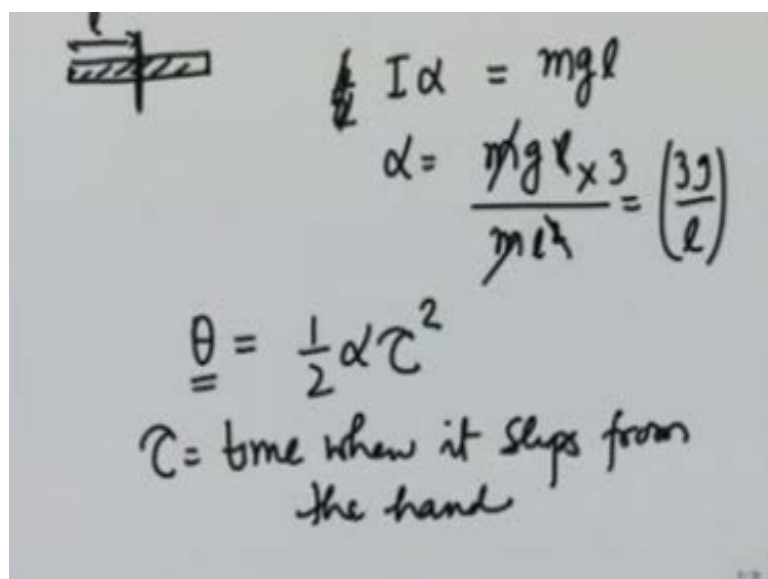

Can I explain this in fact there is a very famous book based on such a thing the book is known as why the toast lands jelly side down. It has been generally observed if you apply jam or butter or jelly on your toast, if it drops from your hand it roughly the jelly side always goes down. Let us try to understand this using our rotational dynamics.

(Refer Slide Time: 12:42)

So, roughly I will take this book let which is let us say of the order of magnitude about twenty or fifteen centimeters wide. I was holding it here, what it did was first it went down like this it rotated about this point. Until it reach an angle when it slipped off. Once it slips off it starts falling down and falling down it rotates. What we observed it rotates roughly by 180 degrees. Why roughly if even if it is 150 it will fall down the other side down even if it 200 will fall down the other side now. So, let us try to understand this.

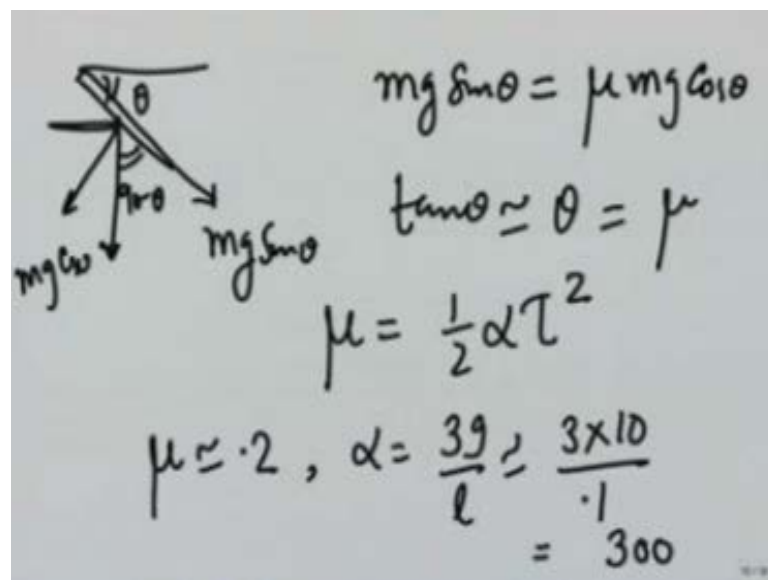

(Refer Slide Time: 13:42)

First step is when the booklet is like this, let the length the distance of the center of mass from the pivot point where I am holding it be l . Then it experiences a force mg at the center of mass and a torque $m g l$. Therefore, it should have an angular acceleration which should be $1/2$ which should be I times α . α would be equal to $m g l$ divide it by I which is ml^2 over 3 , l drops out m drops out. So, the angular acceleration is roughly $3g$ over l .

It covers an angle θ which will be equal to $1/2 \alpha \tau^2$. Well let me write τ as the time when it slips from the end. So, θ is a free $\alpha \tau^2$ what should be the value of θ . We know from mechanics that if a body is at an angle.

(Refer Slide Time: 15:13)

Such that this is θ this is $mg \theta$. This is 90 minus θ this force would be $mg \sin \theta$ this force component would be $mg \cos \theta$. So, if $mg \sin \theta$ roughly becomes μ times, $mg \cos \theta$, then the body is going to slip off my hand. Therefore, I can write $\tan \theta$ roughly equal to θ for θ small equals μ . So, when μ equals $1/2$, $\alpha \tau^2$ this this booklet is going to slip off. Let us take a typical value μ equals roughly point 2 , α is given to be $3g$ over l , which I will take to be roughly equal to 3 times ten over point 1 meters. So, that comes out to be roughly 300 .

(Refer Slide Time: 16:33)

Handwritten mathematical derivation showing the calculation of time τ based on angular displacement μ .

$$\mu = \frac{1}{2} \alpha \tau^2$$
$$.2 = \frac{300}{2} \tau^2$$
$$\tau^2 = \frac{.4}{300} \approx \frac{1}{750}$$
$$\tau = \sqrt{\frac{1}{750}} \approx \frac{1}{30} \text{ seconds}$$

Therefore, I have mu which is equal to 1 half alpha t square point 2 equals 300 divided by 2 whole square or tau the time for it to slip off is going to be point 4 over 300 roughly 1 over 750 tau square. Therefore, tau it was 1 over 750 which I can write as maximum 1 over 30 seconds.

(Refer Slide Time: 17:21)

Handwritten diagram and calculations showing the relationship between angular velocity ω , angular displacement μ , and time t .

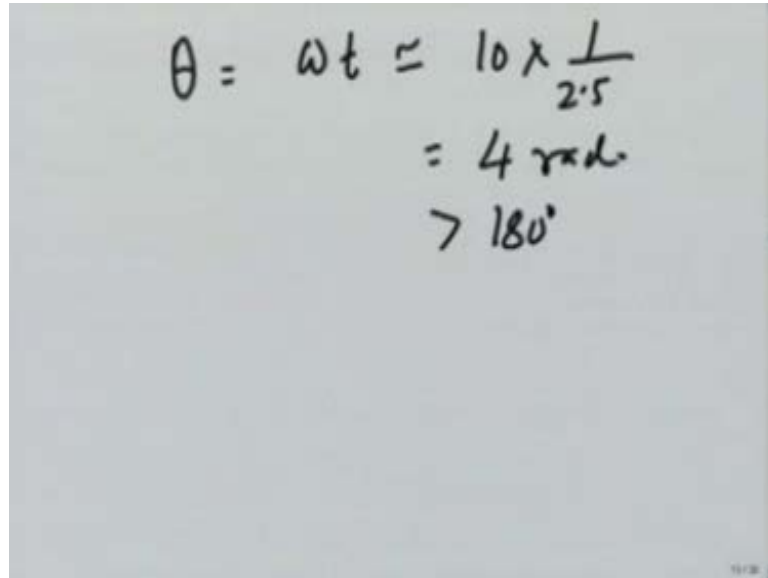

Diagram: A vertical arrow labeled $1m$ indicates a height. A horizontal line represents a toast or booklet at the top. A tilted line represents the toast or booklet slipping off at an angle. The time $\tau = \frac{1}{30} s$ is indicated next to the diagram.

$$\omega = \alpha \tau$$
$$= 300 \times \frac{1}{30}$$
$$= 10 \text{ rad/s}$$
$$\frac{1}{2} g t^2 = 1$$
$$t = \sqrt{\frac{2}{10}} \approx \frac{1}{2.5} s$$

So, we have come up to the point, where the toast or this booklet came here slipped off. This time tau is roughly 1 over 30 seconds. In this time it has gained an omega which is alpha tau and after it slips off that omega remains at constant and makes it rotate. So, this

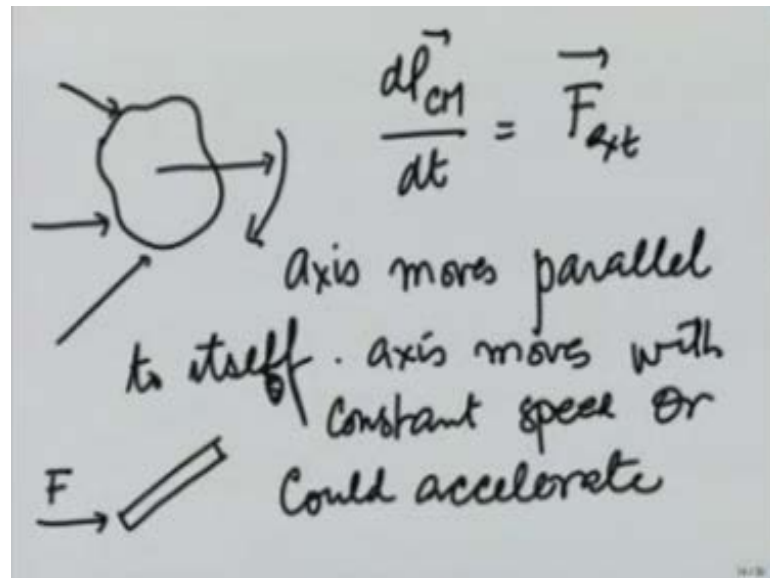

is roughly equal to 1 over 30 times 300 which is equal to 10 radian per second. If this dropped by 1 meter, then the time taken for it to drop could be given by $1/2 g t^2$ equals 1 t equals 2 over 10 square root. Which is roughly 1 over 2.5 seconds.

(Refer Slide Time: 18:22)

$$\begin{aligned}\theta &= \omega t = 10 \times \frac{1}{2.5} \\ &= 4 \text{ rad.} \\ &> 180^\circ\end{aligned}$$

Therefore, you see that the angle by the time it comes down, would be equal to omega times t which is 10 times 1 over 2 point 5 which is 4 radian. Slightly greater than 180. So, that is roughly the angle through which the book rotates and you see it drops the other way. This is an interesting problem when we applied the ideas learnt. So, far having done the problem where the axis was fixed.

(Refer Slide Time: 19:04)

Let us now move on to problems where if I am given a rigid body and I hit it with a force. Its center of mass could move according to $\frac{d p_{cm}}{dt} = \text{force external}$, but also because the forces are distributed over the body, the body itself could change orientation as it moves. For simplicity to start with we will be confined with motion where axis moves only parallel to itself. For example, it could be a rod on a horizontal table being hit by a force F . Then the axis would move parallel to itself to the axis will be perpendicular to the table. Also the axis moves by with constant speed or could accelerate. We want to see how to describe the motion of the rigid body in this case.

(Refer Slide Time: 20:45)

So, let us take a rigid body apply say for force here. One thing is very clear that the center of mass moves according to this equation, that we had already derived. What about the torque, there is a torque about any given point which is not in line of the force and this should be equal to dL/dt about that point. Let us call this point O, could O be any point, should O be CM, should O be a particularly point specified by certain conditions we do not know, but we do wish to apply this equation to describe its orientation change.

This equation we know for sure describes the motion of the center of mass. Usually you must have seen in your twelfth grade or so that O is taken to be the point center of mass, but why that is the question and that is what we wish to answer now. Remember our goal is to apply $dL/dt = \tau_{ext}$ only external when a body is moving.

(Refer Slide Time: 22:06)

So, let us take a general point O and a body that is being applied by several forces. Let us calculate the angular momentum L about O. This by definition is going to be summation $m_i r_i$ with respect to O cross v_i with respect to O. Where I is some general point. Therefore, dL_o/dt and so far we have been doing that, when we take the first derivative $d r_o/dt$ that gives you 0 when crossed with velocity.

So, it comes out to be summation $m_i r_i$ with respect to o cross $d v_i_o$ over $d t$. Let me show you this is $r_i o$. This is r_i , that is the coordinate of the point with respect to an outside origin and this is r_o . Now, v_i with respect to o is nothing but velocity of I th point with respect to outside point minus velocity of o. Therefore, $d v_i_o$ over $d t$ is going to be equal to $d v_i$ over $d t$ with respect to outside point minus $d v_o$ over $d t$.

(Refer Slide Time: 23:54)

$$\frac{d\vec{L}_O}{dt} = \sum_i m_i \vec{r}_{iO} \times \left(\frac{d\vec{v}_i}{dt} - \frac{d\vec{v}_O}{dt} \right)$$

$$m_i \frac{d\vec{v}_i}{dt} = \vec{a}_i m_i = \vec{f}_{i\text{ext}}$$

$$\frac{d\vec{L}_O}{dt} = \sum_i \vec{r}_{iO} \times \vec{f}_{i\text{ext}} = \sum_i m_i \vec{r}_{iO} \times \vec{a}_i$$

Therefore, we get dL_O over dt , that is rate of change of angular momentum with respect to point O is equal to summation $i m_i r_{iO} \times d\vec{v}_i$ over dt minus $d\vec{v}_O$ over dt and I forgotten to put a cross sign here. Let me remind you again, this is my reference plane, this is my body. This is point I, this is some arbitrary point O, this is r_{iO} was derivative using a_{iO} this is r_i and this is r_{iO} , $d\vec{v}_i$ over dt is equal to acceleration of point I, with respect to the outside point, which is an initial point. Therefore, m_i times this is $f_{i\text{ext}}$.

Therefore, I can write dL_O over dt is equal to summation $r_{iO} \times f_{i\text{ext}}$ minus summation $m_i r_{iO} \times a_{iO}$ this is nothing but the acceleration of point O acceleration of point O.

(Refer Slide Time: 25:35)

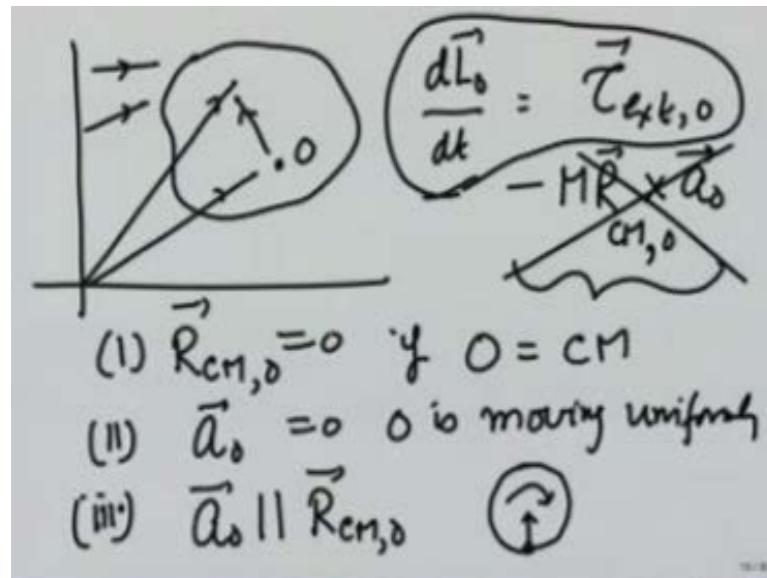

The image shows a handwritten derivation of the rate of change of angular momentum about an arbitrary point O. The first line shows the derivative of angular momentum $\frac{d\vec{L}_O}{dt}$ in a circle, equal to the sum of external torques $\sum_i \vec{r}_{iO} \times \vec{f}_{i,ext}$ minus the sum of terms $\sum m_i \vec{r}_{iO} \times \vec{a}_O$. The second line shows this equal to the external torque $\vec{\tau}_{ext,O}$ in a circle, minus the term $M \vec{R}_{CM,O} \times \vec{a}_O$, where $\vec{R}_{CM,O}$ is the vector from O to the center of mass.

$$\frac{d\vec{L}_O}{dt} = \sum_i \vec{r}_{iO} \times \vec{f}_{i,ext} - \sum m_i \vec{r}_{iO} \times \vec{a}_O$$
$$= \vec{\tau}_{ext,O} - M \vec{R}_{CM,O} \times \vec{a}_O$$

So, what we obtained now is that the rate of change of angular momentum, when angular momentum is taken about an arbitrary point O, which could be in the body which could be accelerating or anything is equal to summation $\vec{r}_{iO} \times \vec{f}_{i,ext}$ only, minus summation $m_i \vec{r}_{iO} \times \vec{a}_O$ of point O itself. This by definition is the external torque with respect to point O no matter what the point O is doing.

So, this is $\tau_{ext,O}$ with respect to point O minus \vec{a}_O is a constant. As far as summation over I is concerned and this is nothing but $M \vec{R}_{CM,O}$ with respect to O. So, if I want that $\frac{d\vec{L}_O}{dt}$ be equal to this only, this term must vanish let me remind you again what we are doing.

(Refer Slide Time: 26:44)

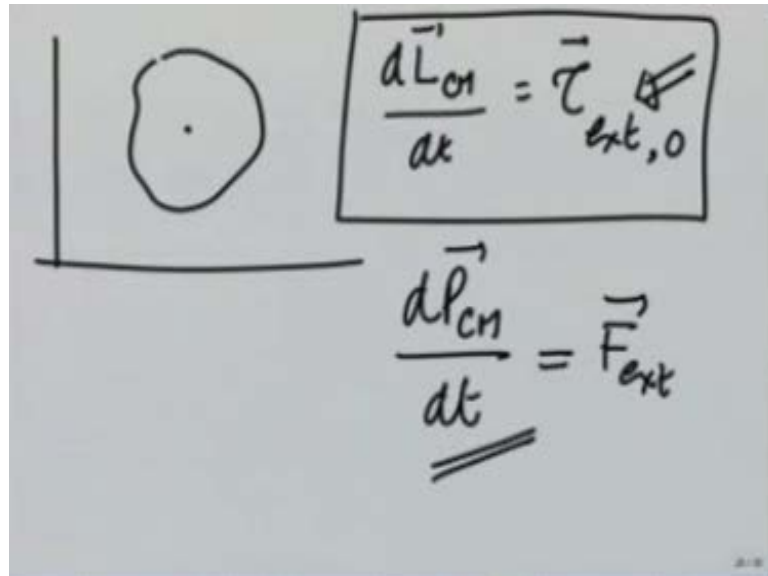

What we are doing is, we are taking a rigid body. Taking an arbitrary point O on this applying some force on the rigid body, calculating the torque due to this force with respect to point O point O could be accelerating moving whatever. Then when I analyze this, what I find is that dL_O/dt is equal to $\tau_{ext,O}$ minus $MR_{CM,O} \times a_O$. I want this term to be 0 I want to choose this point O in such a manner that the last term vanishes. So, that with my eyes closed I can always apply dL/dt equals τ_{ext} only.

This would vanish under 3 conditions number 1 $R_{CM,O}$ itself is 0 and that will be case, if O the point itself is center of mass. This is what you have been doing in your twelfth grade or whatever, that you have been taking torques about center of mass and a mean F been applying dL about CM divided by dt is equal to τ_{ext} about the CM or this should be about O . Number 2 acceleration of point O itself be 0, that means, O is moving uniformly. Third, that acceleration O be parallel to $R_{CM,O}$, that is the point O is accelerating towards the CM itself.

This also you have been doing in your twelfth grade. For example, in a wheel which is rolling, you usually take point about torque about this point and apply dL/dt equals τ . This point is actually accelerating towards the CM. So, therefore, your answers come out to be correct. So, there are only 3 points in a body, in which case this term vanishes and I

can apply with my eyes closed that dL over dt is equal to τ external about that point. We will take a few examples using this equation. So, what we have learnt in general.

(Refer Slide Time: 29:09)

So, far I am restricting myself to only that motion in which the axis moves parallel to itself. That dL about CM dt is equal to τ , external only no other forces need to be taken into account. So, pseudo forces or anything can be applied safely. The motion of the center of mass itself is given by dP_{CM} over dt is equal to F external. These 2 equations are sufficient to describe the entire motion of the body. In that how it is translating that is given by this and how it is changing its orientation is given by this.

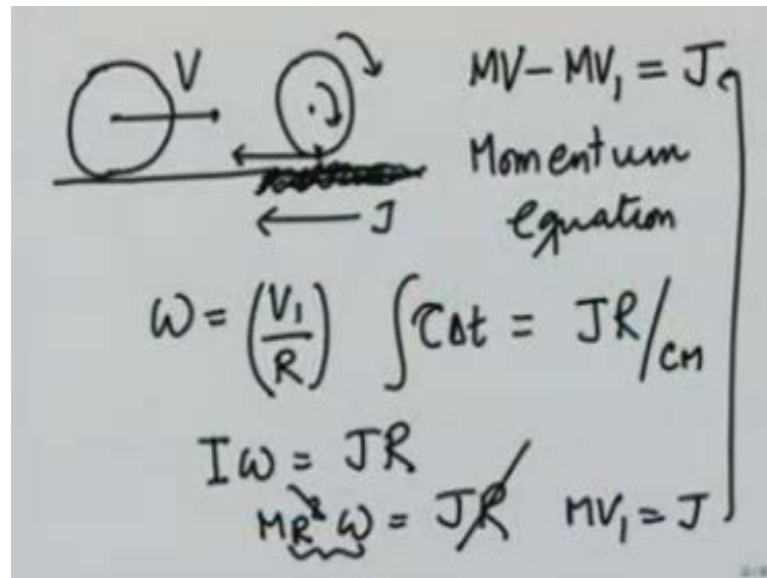

(Refer Slide Time: 30:02)

$J = \int F dt$
 $P_{cm} = J$
 $M V_{cm} = J$
 $V_{cm} = \left(\frac{J}{M} \right)$
 $I_{cm} \omega = \frac{J l}{2}$
 $\frac{M l^2}{12} \omega = \frac{J l}{2}$
 $\omega = \frac{6J}{M l}$

As the first simple example of this. Let us take a rod uniform of length l . Let us hit here with an impulse J , impulse as you would recall is nothing, but integral $F dt$ where F is applied for a very short time. So, this is a very short time Δt let us say. By the moment equation you get that the momentum gained by the rod should be equal to P_{cm} equals J . Therefore, $M V_{cm}$ should be equal to J . So, after the rod is held at a center of mass should move with this velocity.

How about the ω that it obtains. As we have already seen I can safely write. Let me do it right here that the angular momentum it obtains about the center of mass should be equal to the impulse torque impulse direct gains of all the center of mass and that will be $J l / 2$. Therefore, $M l^2 / 12 \omega$ should be equal to $J l / 2$ and it ends up getting ω equals $J / M l \times 6$. So, it rotates as it moves with this angular speed. It moves with this a center of mass moves with this speed. Let us take another example.

(Refer Slide Time: 31:52)

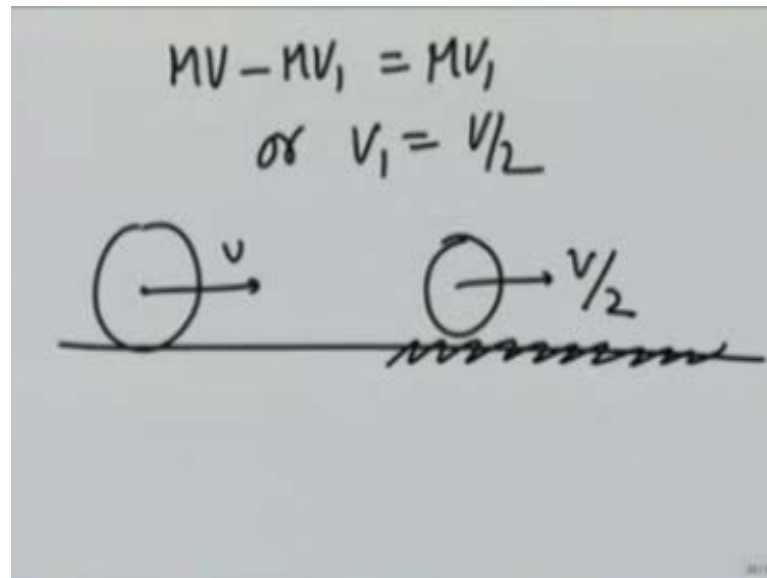

Let us say there is a wheel which is thrown this way with a velocity V . It is moving on a smooth surface there is no friction here. Suddenly it encounters a rough surface. The surface is so rough that starts rolling right away. So, here it was just moving there was no rotation there is no rotation of the wheel about the center of mass. As soon as it hit this rough place it started rotating rolling.

So, at its lowest point was stationary at that point. What about it is rolling speed. So, let us see, what has happened the moment it hits this rough patch it gets an impulse J in this direction initially if it was moving with momentum V . Its momentum now gets reduced because of this impulse. So, that is that comes from momentum equation. Not only that if it is rolling, then it should also be rotating about the center of mass with the speed V_1 over R . Therefore, it has gained an angular momentum about the center of mass, where does this angular momentum come from.

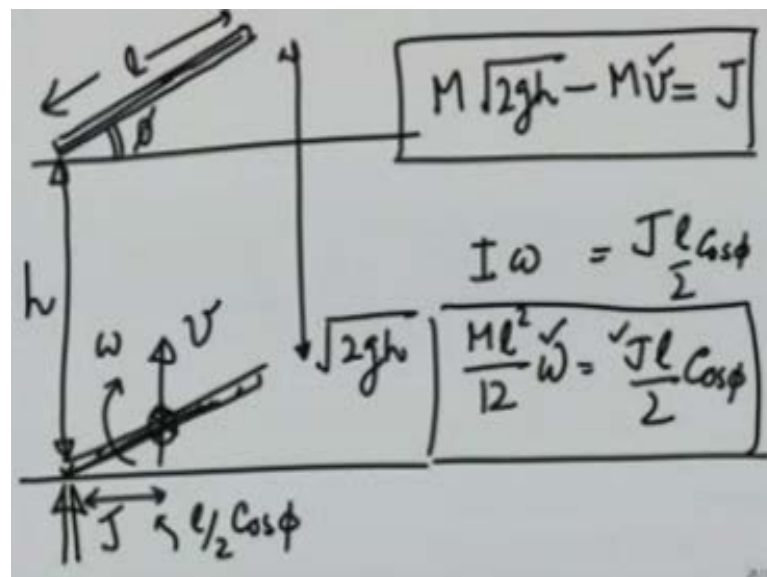

That angular momentum comes from the impulse that it brought here. So, the torque impulse it got is equal to J times R with respect to center of mass. So, the angular momentum it should obtain about the center of mass should be equal to J times R and this tells you I is MR^2 ω is equal to J times R , R cancels. R times ω is V_1 . So, MV_1 equals J .

(Refer Slide Time: 34:15)

Therefore, putting this in this equation I get MV minus MV_1 equals MV_1 or V_1 equals V over 2. So, as soon as this wheel which is moving the speed v , without rolling on a smooth surface hits a rough surface here, it will start rolling with a speed V over 2.

(Refer Slide Time: 34:41)

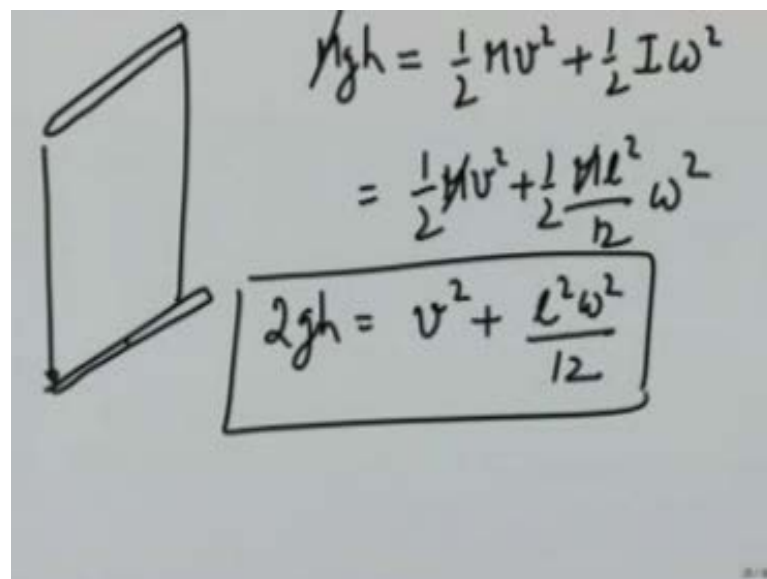

As a third example let me take a rod and you must have seen this. If you sometimes drop things. Let this initial angle from the horizontal be ϕ and let this height from the ground be h and let it drop you must have seen it happen at home. If you drop something like this, it goes back and forth and you hear a voice tuck tuck tuck tuck tuck tuck. So, what I

want to know is after it hits the floor and suppose no energy is lost, what will be its rebound velocity and what will be its rebound omega.

When it drops from a height h, when reaches here as velocity is going to be the square root of 2 g h. When it hits here, there is an impulse that acts here let that be called J. So, I am going to have square root of 2 g h times the mass of the rod minus MV, this is loss and the momentum that should be U to J. That is from momentum equation.

Similarly, now I apply the torque equation about the center of mass, which again the safest point to apply it for. This J gives you a torque impulse this distance is going to be l over 2 cosine of phi, if the length of the rod is l. Therefore, torque impulse is going to be J l divided by 2 cosine of phi and this must give it an angular momentum about center of mass, I omega or $Ml^2 \omega^2 / 12$ is equal to J l over 2 cosine of phi. That is equation number 2. I have 3 unknown v, omega and J. So, I need 1 more equation and that comes from energy conservation.

(Refer Slide Time: 37:08)

The image shows a hand-drawn diagram of a rod of length l and mass M at an angle. To the right of the diagram, the following equations are written:

$$Mgh = \frac{1}{2} Mv^2 + \frac{1}{2} I\omega^2$$

$$= \frac{1}{2} Mv^2 + \frac{1}{2} \frac{Ml^2}{12} \omega^2$$

The final equation is boxed:

$$2gh = v^2 + \frac{l^2 \omega^2}{12}$$

The energy conservation tells me that the energy that it gained, while being topped. The kinetic energy it gained is going to be equal to M g h and that should be equal to its energy right after we and that is going to be 1 half MV square plus 1 half I omega square, which is equal to 1 half MV square, plus 1 half MI square over 12 omega square.

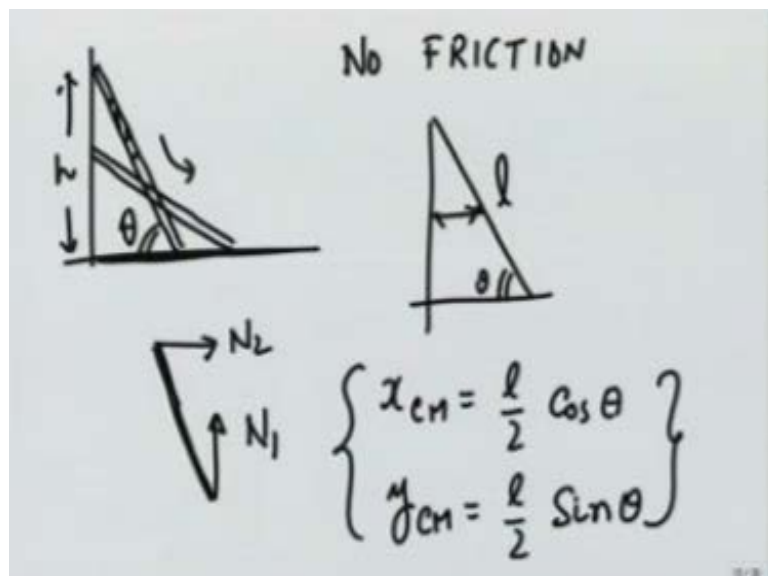

M cancels and therefore, you get $2gh$ equals v^2 plus $l^2 \omega^2$ over 12. So, now I have got 3 equations to solve to get my answers the 3 equations are.

(Refer Slide Time: 38:03)

$$\left\{ \begin{array}{l} M\sqrt{2gh} - MV = J \\ \frac{Ml^2}{12} \omega = \frac{Jl}{2} \cos \phi \\ 2gh = v^2 + \frac{l^2}{12} \omega^2 \end{array} \right.$$

$M\sqrt{2gh}$ minus MV equals J , then I have $Ml^2 \omega$ equals $Jl \cos \phi$. Third equation I have is $2gh$ is equal to v^2 plus $l^2 \omega^2$ over 12. Substituting things properly I can get my answers from this and this I leave as an exercise for you to solve. As a last example I take is a very interesting 1 and very famous one.

(Refer Slide Time: 38:48)

It is if I have a ladder leaning against a wall and on the floor here. Suppose, there is no friction. In the ladder, obviously, would start slipping like this. The question is, if initially it was at height h , at what height does the upper end of the ladder leave the wall. If I make a free body diagram for the ladder, there is going to be a reaction N_1 here and N_2 here. The point at which N_2 vanishes is going to be the point where the upper end has left the wall.

So, what we want to determine is N_2 and make it 0 to find this out. Let us see what is happening as the ladder comes down. As the ladder comes down its center of mass has moved down, not only that, the ladder has rotated about the center of mass. So, it has both a translational as well as a rotational motion. However, all I need to describe its complete motion is this angle it makes with the floor because the center of mass of the ladder is going to be given by this itself.

So, let us make this picture again. There is a ladder of length l , if this angle is θ center of mass is right here. You can see that x_{cm} is going to be $l/2 \cos \theta$ this is $x_{cm} = l/2 \cos \theta$ and y opposite center of mass is going to be $l/2 \sin \theta$.

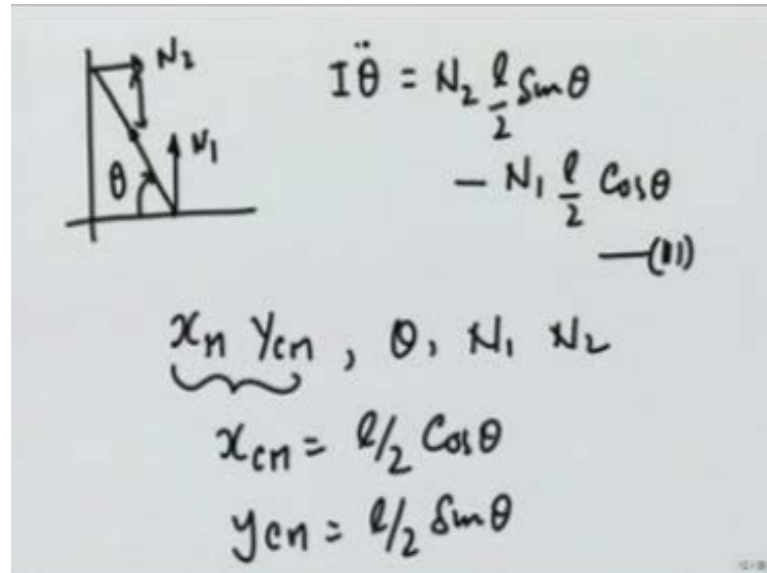

(Refer Slide Time: 40:58)

So, for this ladder I have x_{cm} is equal to $l/2 \cos \theta$ and y_{cm} is equal to $l/2 \sin \theta$ this is N_1 this is N_2 . How about the equations of motion mass of the ladder times x_{cm} double dot is. Obviously, going to be N_2 this is X direction this is y direction. Mass of the ladder y_{cm} double dot is going to be equal to $N_1 - Mg$.

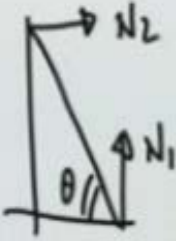

That is for the translation of the center of mass, equation 1 equation 2. On the other hand it also rotates as it moves and it is rotating like this.

(Refer Slide Time: 42:11)

For the rotational motion N_1 N_2 since we are taking theta like this, we will write the equation that way. I am going to have $I \ddot{\theta}$ about the center of mass is going to be equal to N_2 times this, distance which is $\frac{1}{2} \sin \theta$ minus N_1 $\frac{1}{2} \cos \theta$. This is 1 equation number three. So, I have 3 equations, but unknown seem to be more x_{cm} y_{cm} θ N_1 and N_2 . However, x_{cm} and y_{cm} are not independent because as we saw x_{cm} is equal to $\frac{1}{2} \cos \theta$ and y_{cm} this equal to $\frac{1}{2} \sin \theta$.

(Refer Slide Time: 43:24)

$$\begin{aligned}x_{cm} &= \frac{l}{2} \cos \theta \\ \dot{x}_{cm} &= -\frac{l}{2} \sin \theta \dot{\theta} \\ \ddot{x}_{cm} &= -\frac{l}{2} \sin \theta \ddot{\theta} \\ &\quad - \frac{l}{2} \cos \theta \dot{\theta}^2\end{aligned}$$
$$y_{cm} = \frac{l}{2} \sin \theta$$
$$\dot{y}_{cm} = \frac{l}{2} \cos \theta \dot{\theta}; \quad \ddot{y}_{cm} = \frac{l}{2} \cos \theta \ddot{\theta} - \frac{l}{2} \sin \theta \dot{\theta}^2$$

Let us now write expressions for N_1 and N_2 . Let me just make sure that N_1 and N_2 are the ones that I am taking, x_{cm} is equal to $\frac{l}{2} \cos \theta$. Therefore, \dot{x}_{cm} is equal to $-\frac{l}{2} \sin \theta \dot{\theta}$, and therefore, \ddot{x}_{cm} is equal to $-\frac{l}{2} \sin \theta \ddot{\theta} - \frac{l}{2} \cos \theta \dot{\theta}^2$.

Similarly, let us derive \ddot{y}_{cm} , y_{cm} is equal to $\frac{l}{2} \sin \theta$. Therefore, \dot{y}_{cm} is equal to $\frac{l}{2} \cos \theta \dot{\theta}$, and \ddot{y}_{cm} is equal to $\frac{l}{2} \cos \theta \ddot{\theta} - \frac{l}{2} \sin \theta \dot{\theta}^2$. Therefore, we can write expressions for N_1 and N_2 .

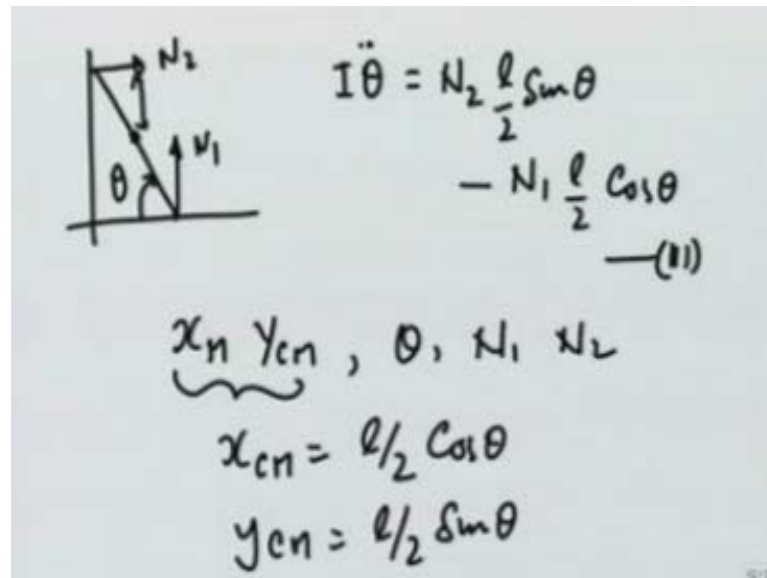

(Refer Slide Time: 44:54)

$$\begin{aligned} N_2 &= M \ddot{x}_{cm} \\ &= M \left(-\frac{l}{2} \sin \theta \ddot{\theta} - \frac{l}{2} \cos \theta \dot{\theta}^2 \right) \quad \text{---(1)} \\ N_1 &= Mg + M \ddot{y}_{cm} \\ &= Mg + M \left(\frac{l}{2} \cos \theta \ddot{\theta} - \frac{l}{2} \sin \theta \dot{\theta}^2 \right) \quad \text{---(1)} \\ I \ddot{\theta} &= N_2 \frac{l}{2} \sin \theta - N_1 \frac{l}{2} \cos \theta \end{aligned}$$

N_2 would be equal to M times x_{cm} double dot which is M minus 1 over 2 sin theta, theta double dot minus 1 over 2 cosine theta, theta dot square. N_1 would be equal to Mg plus M y_{cm} double dot which gives me Mg plus M 1 over 2 cosine theta, theta double dot minus 1 over 2 sin theta, theta dot square. Let us see, if I substitute it for y theta double dot correctly y_{cm} double dot correctly and I get.

So, these are equations that give me N_1 and N_2 . Similarly, $I \theta$ double dot is equal to N_2 1 over 2 sin theta minus N_1 , 1 over 2 cosine theta as we wrote earlier let us check that.

(Refer Slide Time: 46:22)

I theta double dot is $N_2 \frac{l}{2} \sin \theta$ minus $N_1 \frac{l}{2} \cos \theta$. Now, if I substitute for N_1 and N_2 here let us see what do we get.

(Refer Slide Time: 46:36)

We get, I theta double dot is equal to $\frac{1}{2} \sin \theta N_2$ is minus $\frac{Ml}{2} \sin \theta$, theta double dot minus $\frac{Ml}{2} \cos \theta$, theta dot square plus Mg plus $\frac{Ml}{2} \cos \theta$, theta double dot minus $\frac{Ml}{2} \sin \theta$, theta dot square times minus $\frac{1}{2} \cos \theta$ of theta.

Let us see, what do we get when we add these two. So, on the left hand side I get Ml^2 over 12 θ double dot is equal to minus $Mg l$ over 2 cosine of θ that takes care of this term. Then I am going to have minus Ml^2 over 4 cosine square θ coming from here, minus Ml^2 over 4, sin square θ coming from here. That will give me minus Ml^2 over 4 θ double dot that takes care of this term and this term.

Finally, I am going to have plus Ml^2 over 4 sin θ , cosine θ , θ dot square from here and plus Ml^2 over 4 sin θ cosine θ , θ dot square from here. So, that term cancels. So, this is my final equation when I substitute it for N_1 and N_2 into the equation for torque.

(Refer Slide Time: 49:10)

The image shows a handwritten derivation on a whiteboard. The first equation is
$$\left(\frac{Ml^2}{12} + \frac{Ml^2}{4}\right) \ddot{\theta} = -\frac{Mgl}{2} \cos \theta$$
 where the two fractions in the parentheses are grouped together with a curly brace. The second equation is
$$\frac{Ml^2}{3} \ddot{\theta} = -\frac{Mgl}{2} \cos \theta$$
. The third equation is
$$\ddot{\theta} = \frac{d}{d\theta} \left(\frac{\dot{\theta}^2}{2} \right)$$
. The final equation is
$$\frac{1}{2} \frac{Ml^2}{3} \frac{d}{d\theta} (\dot{\theta}^2) = -\frac{Mgl}{2} \cos \theta$$

If I take this over to the other side I am going to get Ml^2 over 12 plus Ml^2 over 4, θ double dot is equal to minus $Mg l$ over 2 cosine of θ . Let us check that if that is correct and that is correct. This is Ml^2 over 3, θ double dot is equal to minus $Mg l$ over 2, cosine of θ . I want to integrate this equation and therefore, I am going to write θ double dot as equal to d over $d\theta$ of θ dot square over 2.

Therefore, this equation becomes $\frac{1}{2} \frac{Ml^2}{3} \frac{d}{d\theta} (\dot{\theta}^2) = -\frac{Mgl}{2} \cos \theta$.

(Refer Slide Time: 50:16)

The image shows a handwritten derivation on a whiteboard. At the top, the equation $\frac{Ml^2}{3} \dot{\theta}^2 = -Mgl \int_{\theta_0}^{\theta} \cos \theta d\theta$ is written. Below it, the integral is evaluated to give $= Mgl (\sin \theta_0 - \sin \theta)$. A large curly bracket on the right side of the equations groups them together. Below the bracket, the text reads: "Change in PE of the ladder = KE of the ladder = KE|cm + KE|ab cm".

That this 2 cancels and that gives me and that is $M g l \sin \theta_0 - \sin \theta$. This is the final equation that I get. Note here this is really nothing but the energy conservation equation. I would leave it for you to find out that. The change in PE of the ladder is equal to the KE of the ladder which is equal to KE of c m plus KE about c m would directly lead you to this equation, but I wanted to derive this equation using equations of motion.

Nonetheless this equation is now the equation that would lead to the answer. So, please try this that derive this directly from the energy conservation equation. This divided by 2 would give you the change in the potential energy and these 2 terms together would give you this term.

(Refer Slide Time: 51:55)

$$\left(\frac{Me^2}{12} + \frac{Me^2}{4}\right) \ddot{\theta} = -\frac{Mgl}{2} \cos \theta$$
$$\frac{Me^2}{3} \ddot{\theta} = -\frac{Mgl}{2} \cos \theta$$
$$\ddot{\theta} = \frac{d}{d\theta} \left(\frac{\dot{\theta}^2}{2} \right)$$
$$\frac{1}{2} \frac{Me^2}{3} \frac{d}{d\theta} (\dot{\theta}^2) = -\frac{Mgl}{2} \cos \theta$$

So, I have $\frac{Me^2}{3} \dot{\theta}^2$ is equal to $Mgl \sin \theta - \int Mgl \cos \theta d\theta$. So, I get the value of $\dot{\theta}^2$. Similarly, I already have Mgl , the value for $\ddot{\theta}$ and if I substitute this and the value for $\dot{\theta}^2$ I will get an expression for $\ddot{\theta}$. Let us go to the expression for $\ddot{\theta}$. $\ddot{\theta}$ was equal to $-\frac{Mgl}{2} \cos \theta$, $\dot{\theta}^2$ and let us substitute.

Let us cancel this, let us cancel M and this gives me $\dot{\theta}^2$ is equal to $3g \sin \theta - \int 2g \cos \theta d\theta$. Similarly the equation for $\ddot{\theta}$ which we had derived earlier this one. $\frac{Me^2}{3} \ddot{\theta}$ equals $-\frac{Mgl}{2} \cos \theta$ let us write that. $\frac{Me^2}{3} \ddot{\theta}$ is equal to $-\frac{Mgl}{2} \cos \theta$. Let me make sure this is the equation.

(Refer Slide Time: 53:53)

$$\frac{Ml\dot{\theta}^2}{3} = Mgl(\sin\theta_0 - \sin\theta)$$
$$N_2 = -\frac{Ml}{2}\sin\theta\ddot{\theta} - \frac{Ml}{2}\cos\theta\dot{\theta}^2$$
$$\dot{\theta}^2 = \frac{3g}{l}(\sin\theta_0 - \sin\theta)$$
$$\frac{Ml\ddot{\theta}}{3} = -\frac{Mgl}{2}\cos\theta \Rightarrow \ddot{\theta} = -\frac{3g}{2l}\cos\theta$$

Ml square over 3 always minus mgl over 2 cosine theta. Gives me M cancels, gives me theta double dot is equal to minus 3 divided by 2 g over 1 cosine of theta. Substituting these in the expression for N_2 here we get.

(Refer Slide Time: 54:26)

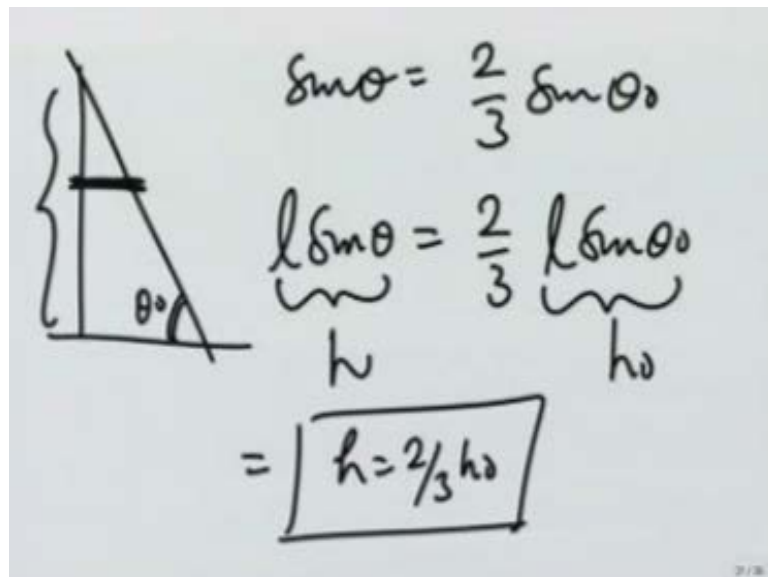

$$N_2 = -\frac{Ml}{2}\sin\theta\left(-\frac{3g}{2l}\cos\theta\right)$$
$$-\frac{Ml}{2}\cos\theta\left(\frac{3g}{l}(\sin\theta_0 - \sin\theta)\right)$$
$$= +\frac{3}{4}Mg\cos\theta\sin\theta$$
$$-\frac{3}{2}Mg\cos\theta\sin\theta_0 + \frac{3}{2}Mg\cos\theta\sin\theta$$

N_2 is equal to minus Ml over 2 sin theta. Let me substitute for theta double dot which is minus 3 over 2. G over 1 cosine of theta and the next term is minus Ml over 2 cosine theta. Minus Ml over 2 cosine of theta and for theta dot square I get $3g$ over 1 sin theta 0 minus sin theta. $3g$ over 1 sin theta 0 minus sin theta. So, this gives me minus 3, this 1

cancels $\frac{3}{2} Mg \cos \theta \sin \theta$ minus $\frac{3}{4} Mg \cos \theta \sin \theta$. This also cancels $\frac{3}{2} Mg \cos \theta \sin \theta$, minus minus plus $\frac{3}{2} Mg \cos \theta \sin \theta$.

Let us add all of them together and we get N_2 is equal to minus $\frac{3}{2} Mg \cos \theta \sin \theta$ plus $\frac{3}{4} Mg \cos \theta \sin \theta$ plus $\frac{3}{2} Mg \cos \theta \sin \theta$ is $\frac{9}{4} Mg \cos \theta \sin \theta$. The point where the ladder leaves the wall N_2 is 0 and this gives me $\frac{3}{2} \sin \theta$ is equal to $\frac{9}{4} \sin \theta_0$, $\sin \theta$ or $\sin \theta$ equals $\frac{2}{3} \sin \theta_0$. So, if we start with an angle θ_0 at $\sin \theta$ equals $\frac{2}{3} \sin \theta_0$ a ladder would leave the wall. So, let us see the picture again.

(Refer Slide Time: 57:13)

This is θ_0 at $\frac{2}{3}$ of $\sin \theta_0$. That means, with a height $\frac{2}{3}$ of the original height the wall and ladder would separate. So, $\sin \theta$ equals $\frac{2}{3} \sin \theta_0$ or $L \sin \theta$ is equal to $\frac{2}{3} L \sin \theta_0$, $L \sin \theta_0$ is the initial height. This is the height at which the ladder leaves the wall. So, h equals $\frac{2}{3}$ the original height a wall leaves. A wall and ladder separate. So, this is another example of how the combination of translational and rotational motion can be solved.

(Refer Slide Time: 58:00)

$$\frac{d\vec{L}}{dt} = \vec{\tau}_{\text{ext}}$$
$$\frac{d\vec{L}_O}{dt} = \vec{\tau}_{\text{ext}}$$

$O \rightarrow \text{CM}$
→ uniformly moving point
→ acc. towards CM

So, what we have done in this lecture so far, is considered various applications of the equation dL over dt equals τ external. In those problems where the axis of rotation remains fixed or it translates parallel to itself. In that case we saw that we apply dL over dt is equal to τ external, where O is either the CM or a uniformly moving point or accelerating towards CM.

The safest point to take always a CM because that you are sure off. With these we got certain solve certain interesting problems. You can keep making problems more complicated, but the application remains basically of these equations. What I would urge you now is apply these to as many difficult problems as you can. Good reference books to find such problems are Merriam dynamics and Kleppner and Kolenkow's of introduction to mechanics.
