**Remote Sensing and GIS Application in Agriculture and NRM - Part 03**

So, in continuation of the topic Remote Sensing and GIS Application in agriculture and NRM, in this part 3 we will be discussing about the role or uses of remote sensing in agriculture. We mentioned it, discussed it also that how different way remote sensing and GIS can be useful for various purposes. Land use and capability we have discussed about. Now, today we will look at that how remote sensing can actually help in studying different aspect of agriculture.

(Refer Slide Time: 01:06)

- RS in agriculture**
- ❑ RS provides several types of spatial information that include soil, Land Use Land Cover (LULC), vegetation indices (VI), soil moisture, a fraction of absorbed photosynthetically active radiation (FAPAR), crop biophysical condition data like leaf area index (LAI), crop height, canopy cover, stem width, above-ground biomass, crop biochemical parameters like leaf color, chlorophyll content, etc. which are crucial for crop model performance for computing evapotranspiration, biomass yield.
  - ❑ RS can also represent the missing data and describe crop conditions throughout various crop growth stages
  - ❑ RS can minimize the unpredictability of spatial information associated with the crop models
  - ❑ The RS application in agriculture began with the large area crop inventory experiment (LACIE) using LANDSAT data to estimate wheat production
  - ❑ Unmanned aerial vehicle (UAV) system has become a modern technology for crop water status detection, plant density estimation, crop biophysical parameter estimation, and several other applications
  - ❑ UAVs can provide very high-resolution images
  - ❑ Limitations of UAV are, such as small area coverage and insufficient flight time

Remote sensing, it provides several types of spatial information that we have already discussed like information about soil, Land Use Land Cover, vegetation index, soil moisture. So, a fraction of the absorbed photosynthetically active radiation that we call FAPAR, crop biophysical condition data like leaf area index, crop height, canopy cover, stem width, above-ground biomass, crop biochemical parameters like your leaf color, chlorophyll content or various other aspects which are crucial for crop model performances for computing evapotranspiration, biomass yield.

Because these are the aspects that we need to know, need to study about agriculture. And if you recall that in the modeling lectures, we discussed in great detail that how inputs comes from different climate model, remote sensing or information. These all also can come and can be integrated today in a couple manner.

So, we also discussed if you recall that, that how a coupling of hydrological model, crop model can also be done and utilization of artificial intelligence, GIS, remote sensing these days are possible. Now, remote sensing can also represent the missing data and can describe the crop conditions throughout the various crop growth stages. I have given you often the example of rice because most of us actually well aware of the rice crop and rice crop has different stages and very different color and also structure.

So, remote sensing can be used very efficiently to find out missing data and also the crop conditions across the different crop growth stages. Remote sensing can also minimize the unpredictability of spatial formation, especially, which are associated with crop models. Remember, in crop modeling lectures we discussed that, that in crop modeling we try to mimic the natural condition and we try to close as much as possible.

They are also remote sensing play important role. The informations of remote sensing can be used in crop model and the resolutions or the spatial informations about a particular crop in a certain area actually can be improved by the help of good quality remote sensing data. The remote sensing application in agriculture began with the Large Area Crop Inventory Experiment which we call LACIE. LACIE used LANDSAT data to estimate crop production.

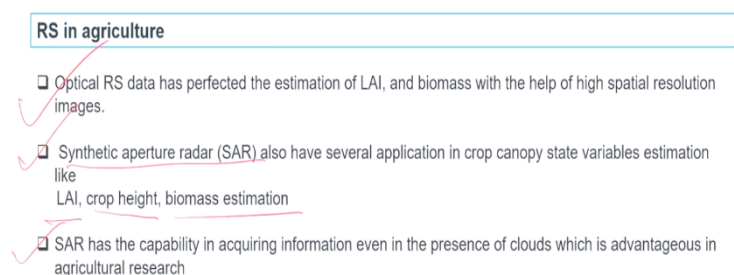

So, especially, in developed country where you have huge amount of land covered under single crop, there certainly will get very very useful remote sensing information. But in case of India, here as the land size is small, probably in one land to the very next line you can have 2 different type of crops. Yet remote sensing can help us to understand the different crop coverage in an area.

Unmanned Aerial Vehicle, (UAV), all of you are aware of UAV system has become very popular in various developed country as well as it is now slowly coming into use in our country because UAV technology. UAV system can be used for crop water status detection means how much water is there whether you need to apply irrigation or not.

One of the major concern in case of irrigated agriculture is that we irrigate even when it is not required. And irrigation means utilization of energy, electricity. Huge amount of groundwater wastage. So, UAV can help you to understand the crop water status and thus you will be able to actually irrigate the field when it is needed. It can also help you to estimate plant density, crop biophysical parameter and also various other aspect of agriculture.

UAV can provide us very high-resolution images. And as if we get high-resolution images, certainly, our evaluation of the cropping area, estimation of various resources, everything will be almost error free. But having said that there are few limitations of UAV as well such as it has a very small area coverage and also very insufficient flight time. Means, after certain time it has to come down you have to get it down and then again send it up. Because there are also certain issues with its energy, how long it can actually fly. So, these are few issues which are still being addressed at the R&D level.

(Refer Slide Time: 06:48)

- 
- ☒ Optical RS data has perfected the estimation of LAI, and biomass with the help of high spatial resolution images.
  - ☒ Synthetic aperture radar (SAR) also have several application in crop canopy state variables estimation like LAI, crop height, biomass estimation
  - ☒ SAR has the capability in acquiring information even in the presence of clouds which is advantageous in agricultural research

139

Optical remote sensing data has almost perfected the estimation of leaf area index and biomass with the help of high spatial resolution images. Because if you get high-resolution images then actually it is very very easy to actually capture the real fact of the ground. Better the quality of the picture better will be your outcome of the analysis.

Now, SAR also have several application, Synthetic Aperture Radar has also have several application in crop canopy state variable estimation like leaf area index, crop height, biomass estimation. SAR also has the capability in acquiring information even in the presence of clouds and that is advantageous in case of agriculture research, especially, Indian agriculture

where you get often cloud cover, we have a long rainy season also and various parts gets rains in different time. So, in our situation SAR can be a useful tool.

**Satellite-based estimation of evapotranspiration**

❖ **Surface Energy Balance Algorithm for Land (SEBAL)**

Based on the surface energy balance

The model computes a complete radiation and energy balance along with the resistances for momentum, heat, and water vapor transport for each pixel.

$$\lambda ET = R_n - G - H$$

$\lambda ET$  = Evapotranspiration that is derived in terms of instantaneous latent heat flux

$R_n$  = Net radiation ( $W/m^2$ )

$G$  = Soil heat flux ( $W/m^2$ )

$H$  = sensible heat flux ( $W/m^2$ )

Net radiation is computed from the land surface radiation balance as

$$R_n = (1 - \alpha)R_{sin} + R_{Lin} - R_{Lout} - (1 - \epsilon_0)R_{Lin}$$

Now, satellite-based estimation of evapotranspiration. This is another utilization of satellite-based technology. Surface Energy Balance Algorithm for Land, this is what we call as SEBAL. This is actually used and it is based on the surface energy balance theory. The model, it computes a complete radiation and energy balance along with the resistance for momentum, heat, water vapor transport for each pixel, for each pixel. So, this is the equation that is used for this

Lambda ET is equals to Rn minus G minus H

What are those?

Lambda ET is evapotranspiration that is derived in terms of instantaneous latent heat flux. Rn is net radiation that is the unit. G stands for soil heat flux. H stands for sensible heat flux. And then net radiation is computed the land surface radiation balance as

Rn is equals to (1 minus alpha) multiplied by Rsin plus RLin minus RLout minus (1 minus epsilon 0) multiplied by RLin

So, this particular equation helps you to get the net radiation which is expressed as RLin.

(Refer Slide Time: 09:42)

#### Satellite-based estimation of evapotranspiration (SEBAL)

$R_{sin}$  = Incoming short-wave solar radiation ( $W/m^2$ )

$\alpha$  = Surface albedo

$R_{lin}$  = Incoming long-wave solar radiation ( $W/m^2$ )

$R_{lout}$  = Outgoing long-wave solar radiation ( $W/m^2$ )

$\epsilon_0$  = Land surface emissivity

$G$  is empirically related to NDVI as

$$\frac{G}{R_n} = \frac{T_s}{\alpha} (0.0038\alpha + 0.0074\alpha^2)(1 - 0.98NDVI^4)$$

$T_s$  = Surface temperature (K)

The expression for sensible heat flux is given as

$$H = \rho C_p \frac{dT}{r_{ah}}$$

$\rho$  = Air density ( $Kg/m^3$ )

$C_p$  = Specific heat capacity of air ( $\approx 1004$  J/kg/K)

$dT$  = Near-surface temperature difference (K)

$r_{ah}$  = Aerodynamic resistance to heat transport (s/m)

141

Now,  $R_{sin}$  equal is actually the incoming shortwave solar radiation where  $\alpha$  is the surface albedo,  $R_{lin}$  incoming long wave solar radiation then outgoing long wave solar radiation land surface emissivity  $\epsilon_0$ ,  $G$  is empirically related to NDVI. How?

As  $G$  by  $R_n$  is equal to  $T_s$  by  $\alpha$  and then you have it this particular equation.

$G$  divided by  $R_n$  is equals to  $T_s$  by  $\alpha$  multiplied by 0.0038 multiplied by  $\alpha$  plus 0.0074 multiplied by  $\alpha$  square whole multiplied by 1 minus 0.98 multiplied by NDVI to the power four

Where  $T_s$  stands for surface temperature in Kelvin.

The expression for sensible heat flux is given by this equation.

$H$  is equal to  $\rho$  multiplied by  $C_p$  multiplied by  $dT$  divided by  $r_{ah}$

Where  $\rho$  is the air density.  $C_p$  stands for specific heat capacity of the air,  $dT$  is the near surface temperature difference in kelvin  $r_{ah}$  is the aerodynamic resistance to heat transport. So, these are the different way that you actually get the various estimations under SEBAL calculation.

(Refer Slide Time: 10:52)

#### Satellite-based estimation of evapotranspiration (SEBAL)

In the SEBAL model,  $T_s$  and  $dT$  are related linearly as

$$dT = aT_s + b$$

$a$ ,  $b$  are calibration parameters

Calibrated on the basis of the knowledge of two boundary conditions identified within the image itself where the  $dT$  values can be back-calculated using a known  $H$  at the two pixels

$a$  and  $b$  require a choice of the two pixels, representing the extreme conditions of temperature and humidity, called the hot pixels and cold pixels

The cold pixel is a well-irrigated crop surface with full cover and the surface temperature  $T_s$  close to the air temperature  $T_a$

The hot pixel is a dry bare agricultural field where  $\lambda ET$  is assumed to be 0

The two pixels tie the calculations for all other pixels between these two points.

An iterative way started from neutral stability assumptions is conducted for the sensible heat flux estimation using atmospheric stability corrections

342

In SEBAL model,  $T_s$  and  $dT$  are actually related linearly. As you see here,

$dT$  is equal to  $a$  multiplied by  $T_s$  plus  $b$

is a linear equation  $a$  or  $b$  are calibration parameter and these are calibrated on the basis of the knowledge of 2 boundary conditions identified within the image itself. And  $dT$  values can when we back-calculated using a known  $H$  at the 2 pixels.

So, you have cold pixel and you will have hot pixel. So,  $a$  and  $b$  require a choice of 2 pixel representing the extreme condition of the temperature and humidity. And these 2 extreme conditions, one is hot and the other is cold pixel. The cold pixel is a well irrigated crop surface with full cover and the surface temperature  $T_s$  will be close to the air temperature  $T_a$ .

But the hot pixel is a dry bare agricultural land where  $\lambda ET$  is assumed to be zero. So, this 2 pixel tie the calculation for all other pixels between these 2 points. And iterative way started from the neutral stability assumption is generally conducted for the sensible heat flux estimation and you do it using the atmospheric stability corrections.

(Refer Slide Time: 12:30)

#### Satellite-based estimation of evapotranspiration (SEBAL)

Instantaneous evaporative fraction  $\Lambda$  is computed by

$$\Lambda = \frac{\lambda ET}{\lambda ET + H} = \frac{\lambda ET}{R_n - G}$$

$\Lambda$  is the ratio of the actual to the crop evaporative demand when the atmospheric moisture conditions are in equilibrium with the soil moisture conditions

$\Lambda$  is almost constant within daytime hours, thus allowing the use of as a temporal integration parameter

$G$  can be neglected For timescales of 1 day or longer

At daily timescales,  $ET_{24}$  (mm/d) can be computed as

$$ET_{24} = \frac{86400 \times 10^3}{\lambda \rho_w} \Lambda R_{n24}$$

$R_{n24}$  ( $W/m^2$ ) is the 24 h averaged net radiation

$\lambda$  (J/kg) is the latent heat of vaporization

$\rho_w$  ( $kg/m^3$ ) is the density of water

343

So, SEBAL model, in fact, allow you to understand the different extremes of weather events like humidity, temperature. Because ultimately, you are going to also calculate the evapotranspiration. So, the instantaneous evaporative fraction is computed using this equation.

Lambda uppercase is equals to (lambda ET divided by Lambda ET plus H) plus (ET divided by Rn minus G)

So, the ratio of the actual to the crop evaporative demand, especially, when the atmospheric moisture conditions are in equilibrium with the soil moisture condition. So, that is what is your instantaneous evaporative fraction. Now, this fraction is almost constant within daytime hours and thus it allows to use as a temporal integration parameter.

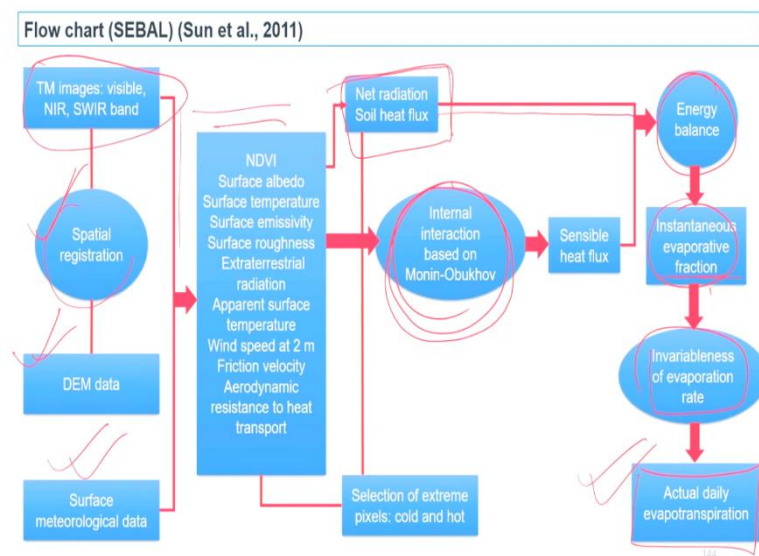

Now,  $G$  can be neglected for time scales of one day or longer. In case of daily time scale, your evapotranspiration for 24 hours can be computed through this equation.

$ET_{24}$  is equals to 86400 multiplied by 1000 multiplied by uppercase lambda  $R_{n24}$  divided by lambda rho w

Here are the details about different parameter. These I am just you know sharing with you because these are the aspect which is required probably when you want to go very deep into remote sensing and GIS.

But under this course I am just giving you some highlights of the application of different satellite-based technologies for natural resource management. So, if you want to get into further detail, if you are interested to learn then you have to take a completely separate course on remote sensing and GIS.

(Refer Slide Time: 14:08)

#### Satellite-based estimation of evapotranspiration (SEBAL)

Instantaneous evaporative fraction  $\Lambda$  is computed by

$$\Lambda = \frac{\lambda ET}{\lambda ET + H} = \frac{\lambda ET}{R_n - G}$$

$\Lambda$  is the ratio of the actual to the crop evaporative demand when the atmospheric moisture conditions are in equilibrium with the soil moisture conditions

$\Lambda$  is almost constant within daytime hours, thus allowing the use of as a temporal integration parameter

$G$  can be neglected For timescales of 1 day or longer

At daily timescales,  $ET_{24}$  (mm/d) can be computed as

$$ET_{24} = \frac{86400 \times 10^3}{\lambda \rho_w} \Lambda R_{n24}$$

$R_{n24}$  (W/m<sup>2</sup>) is the 24 h averaged net radiation

$\lambda$  (J/kg) is the latent heat of vaporization

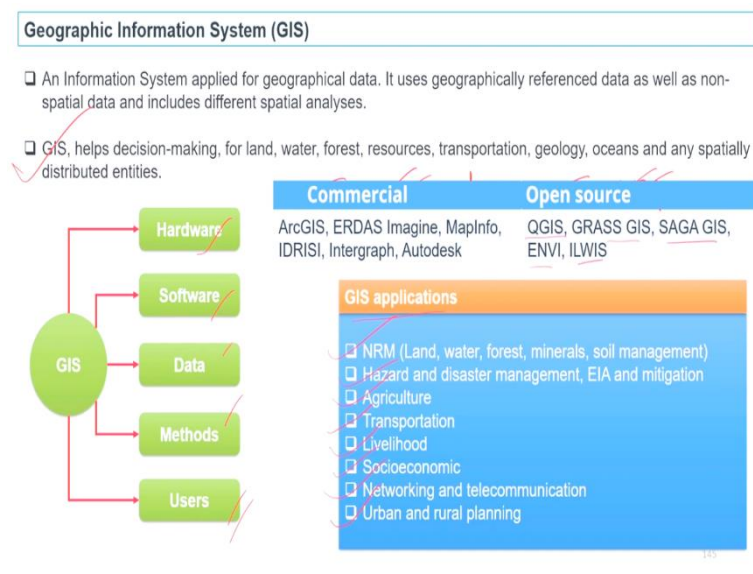

$\rho_w$  (kg/m<sup>3</sup>) is the density of water

Now, if you look at the SEBAL structure, so, it actually starts with your TM image, visible NIR also SWIR band under that whatever information that you are capturing through the satellite spatial registration takes place digital elevation model data is also required. Surface meteorological data also needed.

So, when these are with you then you go for NDVI, surface albedo, surface temperature surface emissivity, all these kinds of analysis or function that you can actually run. Then through this you can get net radiation soil heat flux, you can also get internal interaction based on various equations. Once you get net radiation soil heat flux, you go towards energy balance then instantaneous evaporated fractions that you get which I discussed here.

Once you get instantaneous evaporative fraction then you go to the next stage, invariableness of evaporation rate, and then finally you calculate actual daily evapotranspiration. So, your ultimate aim is to get that per day how much actually water is getting evapotranspired. Because that will actually tells you that how much water is present there and how much water you need to put back into the soil in the form of irrigation or otherwise.

(Refer Slide Time: 15:41)

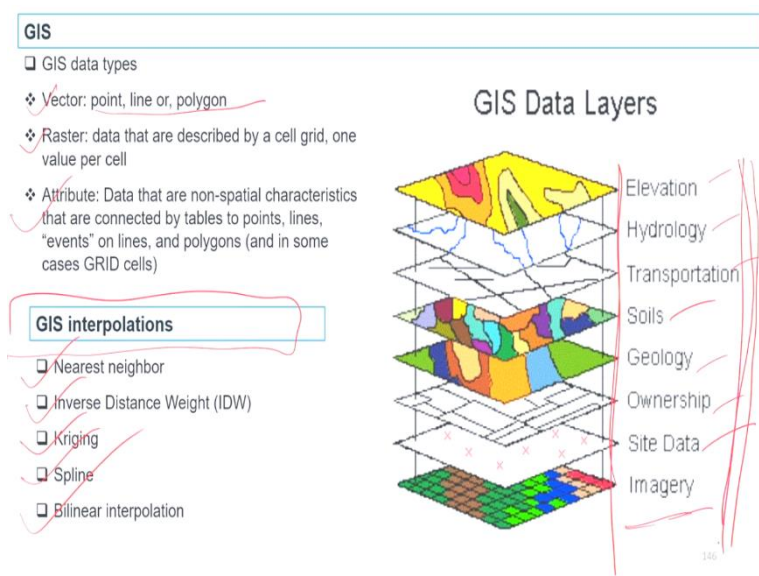

Now, GIS, Geographic Information System. This is a tool information system which is applied for representing your various data analysis in a very user-friendly manner. So, this tool uses geographically reference data as well as non-spatial data and also includes different spatial analysis as well.

GIS also helps in decision-making for land, water, are all natural resources, transportation, even geology, oceans, anything. You can actually see in front of you in a pictorial form. So, for GIS, to work with GIS you need good quality hardware, software, data, various methodology and also skilled manpower.

Now, there are few open source for this GIS tool like ArcGIS, ERDAS, Imagine, Mapinfo, IDRISI, Intergraph, Autodesk. Various commercial also aspects. So, these are actually basically the commercial one and these are the open source. So, ArcGIS, ERDAS, Mapinfo these, one has to buy actually, procure the right to work with. But there are, few are which are available in the free domain like QGIS, GRASS, GIS, SAGA GIS, ENVI, ILWIS.

So, these are some of the software. And then application of GIS are plenty. We already discussed in the previous lectures, in natural resource management, hazard disaster management, agriculture, transportation, livelihood, socioeconomic aspect, networking and telecommunication, urban and rural planning, any kind of decision-making processes GIS plays a very important role.

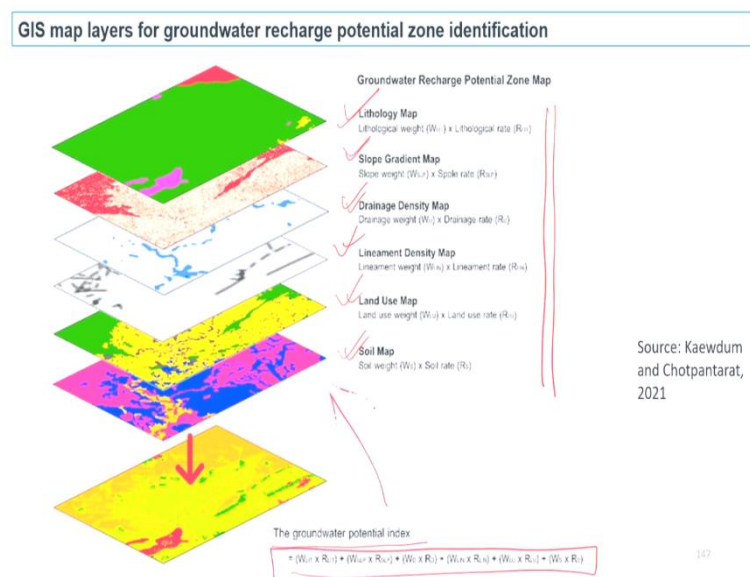

(Refer Slide Time: 17:32)

So, if you look at the data types that GIS tool uses they are basically vector and raster data. Vector data are in the form of point, line or polygon. Raster data that are describing by cell grid, one value per cell. Then you have attribute data that are non-spatial characteristics that are connected by tables to points, lines or events and polygons in some cases also grid cells.

Now, in case of GIS interpolation, if you want to have GIS interpolations then Nearest Neighbor one is method, then Inverse Distance Weight is another method, kriging is one very very popular method then spline, you can do bilinear interpolation. These are various kind of methods that people uses for various kind of interpolations within GIS platform. These are the various GIS data layers in general one can actually see it. So, you have elevation, hydrology, transportation, soils, geology, ownership, site data, imagery. So, various data layers that you can actually put one after the other.

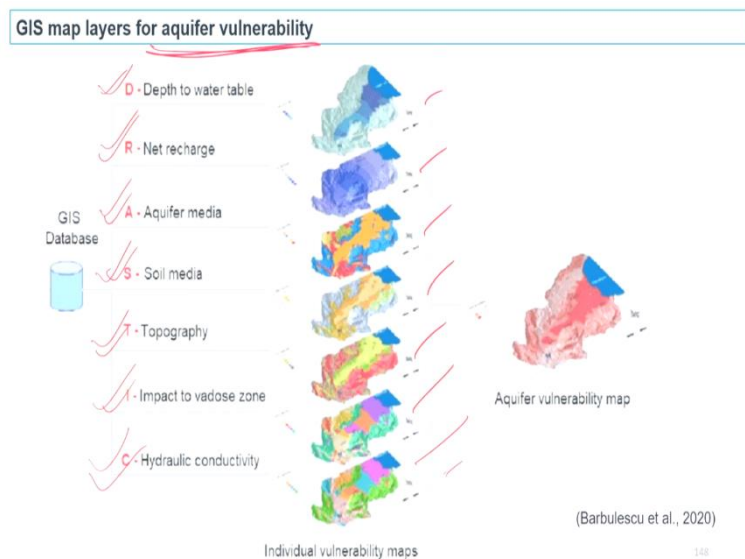

(Refer Slide Time: 18:54)

GIS map layers for groundwater recharge is very interesting and lot of work has been carried out across the world. So, especially for groundwater recharge if somebody wants to study then you can see that you need various layers, means various level, various type of information. Lithology map is one, slope gradient map, drainage density map, lineament density map, land use map and soil map.

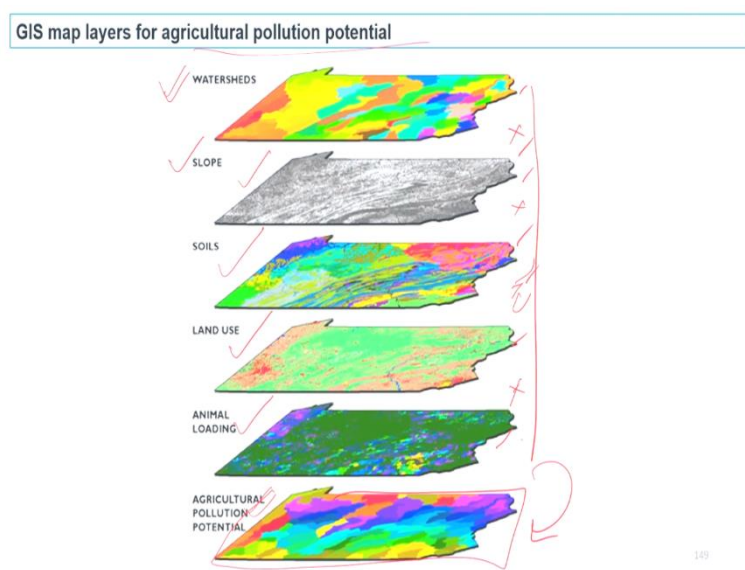

So, all these information layer after layer in GIS actually you put in and then these, all these layers will interact with each other you analyze and then finally you can calculate the groundwater potential index utilizing various layers these are mentioned above. So, in GIS you can actually carry out various kind of interactions also, you can overlay one layer above the others, you can actually find out the interrelation between various layers. So, those kinds of different analysis also are possible within GIS platform.

(Refer Slide Time: 20:13)

GIS map layers of aquifer vulnerabilities, another very interesting field that people actually work a lot. And there are many studies available. So, in understand the aquifer vulnerability, especially, people study in drought prone area, you will find that they will get different information layer, depth of water table, net recharge, aquifer media, soil media, topography, impact to vadose zone, hydraulic conductivity. So, all these layers after layer, they will put and then these layers actually can even interact with each other. Then you can carry out various interactive analysis to find out the aquifer vulnerability.

(Refer Slide Time: 21:02)

There are also lot of studies available using GIS tool; GIS map layers of agricultural pollution potential. So, there people who actually have various layers like watershed, slope, soil, land use, animal loading, agricultural pollution potential the final. So, interaction with all these layers then finally they can find out the agriculture pollution potential through the interactions of various layers of information within GIS platform.

So, this actually gives you very clear-cut information which is visible and this also helps to present your study in a very meaningful manner and also for layman, suppose, people who are not expert of GIS they can see the picture and looking at the maps they can understand, okay, this area is required our attention.

If policy makers, you are sharing your result with the policy makers they will appreciate when you actually show and understanding, your analysis result through this kind of GIS maps. So, that is what I think that these days for any kind of study, especially, in the field of natural resource management GIS plays a very very important role for data representation.
